CHAPTER 26

ALUMINUM Al

Aluminum is a light metal which is relatively abundant in the earth's crust. It is soluble in both acid and alkali and forms a gelatinous insoluble hydroxide at intermedate pH values. Considering its abundance in rocks and soils, it is surprising that so little is known about its environmental effects.

Aluminum analyses up to now have not been required in most effluent monitoring programs. Mine and mill discharge permits usually do not list limits for this metal either. Criteria of 100 ug/l have been proposed for the U.S.A. (EPA, 1972), Ontario (1978), and Quebec for fresh water and 200 ug/l for marine effluents (EPA, 1972).

There are no NPDES standards for Al in effluents discharged to surface waters. Public drinking water standards in Canada and the U.S.A. do not list Al, and 5,000 ug/l Al is the maximum permissable for livestock watering and irrigation according to the EPA (1972).

Some states (New York, for example) are proposing that Al should be monitored in effluents and reported even though it does not have to meet any specific limit at this point.

Limited attention has focussed on aluminum recently since there has been speculation that acid rain leaches it from soils and that some fish species find aluminum toxic and the cause of gill damage. Aluminum was implicated in the decrease of fish stocks in lakes whose pH levels declined as a result of inadequate buffering capacity to neutralize acid inputs. Aluminum mobilized by acid rain would drain into lakes and accumulate by precipitation until the pH of the lake decreased sufficiently to redissolve the precipitates and pose a threat to aquatic organisms. Also, aluminum has been identified in the brains of victims of Alzheimer's Disease--the disease of senility.

The importance of pH was reported by FREEMAN AND EVERHART (1971) who showed that Al toxicity is very pH dependent. BURROWS (1977) reviewed the chemistry, toxicity, and environmental prevalence of aluminum in the aquatic environment. The California Regional Water Quality Control Board, North Coast Region, Order No. 84-108 on waste discharge requirements for NORANDA Grey Eagle Mines, Inc. stipulates that no water shall be discharged into streams or other surface waters. Excess water disposed of through irrigation to a disposal site shall contain no more than 0.5 ppm Al.

Strangely enough, this metal that the California RWQCB considers in need of regulation is grouped as a heavy metal in their classification. The basis for this

limitation for irrigation is not mentioned, and, unquestionably, it is much stricter than agricultural irrigation water standards.

PATTERSON (1979), in a review paper on industry sources and control of metals, lists Al as one of the regulated metals for coal and ore mining which was based on a directory of federal and state water pollution standards prepared by the same author for the Illinois Institute for Environmental Quality. PATTERSON (1979) also shows proposed levels of 0.6 mg/l Al for 30-day averages and 1.2 mg/l Al as the 24-hour maximum for Al within BPCT, BAT, and NSPS regulations.

LARSEN AND ROSS, formerly of the University of Denver, showed two acid mine drainage streams, namely the Idaho drainage tunnel with 10.00 ppm Al and the Montana drainage sample with 904 ppm Al. They indicate that aluminum is readily removed by the addition of lime which is the first step of their two-step process.. In the diagram shown in their paper, however, some Al seems to be left in solution by the time sulfide addition starts. Their diagrams indicate that Al is the first metal to be quantitatively removed as sulfide is added although presumably not as a sulfide.

At the EAST RAND PROPRIETORY MINES LTD. on the Witwatersrand, acid mine drainage pumped from underground at pH 4.5 contained 30 mg Al/l. In the seeded slurry reverse osmosis test this was reduced to 0.5 ppm Al in the product water.

It is known that the very acidic raffinate solutions generated from Witwatersrand ores can contain very high levels of Al (3-5,000 ppm), but these are undoubtably reduced during neutralization. Of some concern is the amphoteric nature of Al which seems to go back into solution readily if the pH of water in contact with the precipitate drops again. One non-Witwatersrand uranium mine also employing an acid leach yields a tailings pond decant solution with 625 ppm Al, and the tailings pond seepage after natural pH adjustment to pH 6.6 has dropped to 12 ppm Al. Aluminum forms soluble hydroxide complexes which means that at high pH levels, it is also rendered soluble; if such water is discharged, it will, on mixing with recovering waters, likely reprecipitate to some extent. Not very much seems to be known about the effects of aluminum in the environment or on the long-term health effects on humans of aluminum in the drinking water. Aluminum is, of course, routinely used for clarification of drinking water by municipalities as alum ($Al_2(SO_4)_3$).

WILMOTH AND SCOTT (1976) showed interesting data for unreferenced acid mine drainage and treatment thereof by several processes. It is interesting that alumina-lime-soda, a process in which aluminum is added to the effluent, actually achieves one of the lowest Al levels in the processed water.

CONCLUSIONS

- Not much is known about aluminum levels in mine and mill effluents. Aluminum was one metal that was overlooked by the PEDCO (1983) Evaluation of Management Practices for Mine Solid Waste Storage, Disposal, and Treatment.

- Most mine/mill effluent analyses do not include aluminum.

- Aluminum is acutely toxic to fish at low levels of around 0.1 mg/l or less, especially at low pH, and is likely to become more of a focal point as a result of studies on the acid rain problem. Aluminum may also be of concern for high pH effluents due to its solubility as a hydroxide complex.

- Seeded slurry reverse osmosis reduced aluminum levels in AMD treatment test from 30 mg/l to 0.5 mg/l.

- Aluminum is precipitated as a hydroxide at around pH 5.5-6. Pilot scale tests of a two-stage lime-sulfide process indicate that Al can be almost quantitatively removed by precipitation.

- More needs to be known about the effects of aluminum in recycled mine and mill process water on metallurgical processes.

INTRODUCTION

Ammonia is a pungent, colorless, alkaline compound NH_3 that is very soluble in water. It is a biologically active compound present in most waters as a normal biological degradation product of nitrogenous organic matter. It is, however, undisputably toxic to fish. Ammonia may also reach ground and surface waters through agricultural drainage after application of ammonia fertilizers and through discharge of industrial wastes containing ammonia as a by-product or wastes from industrial processes using ammonia as a reagent or for pH control. Considering the huge volume of sewage effluents containing around 10-20 ppm NH_3 (NALCO, 1979) and the millions of tons of ammonia fertilizer applied to the land surface annually, it is, at first impression, incongruous to find such tight regulations governing ammonia in minewater discharges.

AMMONIA IN MINING AND MINERAL PROCESSING

Ammonia enters minewater mainly through the use of explosives containing ammonia; e.g., AMFO, which are commonly used. Metallurgical plant effluents may contain ammonia due to its use as a reagent (e.g., in copper and nickel refining) or as a pH modifier (e.g., one copper-lead-zinc flotation plant in Ontario), through sewage plant effluents or even possibly through biological degradation of cyanide in gold mill tailings solutions. Ammonia is also introduced to some uranium mill systems as ammonium sulfate used to elute uranium from ion exchange resins and SX and as NH_4OH to precipitate uranium from the eluates.

Unquestionably, the use of ammonia in metallurgical plants has mostly been replaced by other reagents where appropriate because of the awareness of the damage that ammonia in effluents does to fish.

In the PEDCO (1983) report to the U.S. EPA on Evaluation of Management Practices for Mine Solid Waste Storage Disposal and Treatment, ammonia was analyzed in tailings pond decant and in water extractions from tailings. Quite variable concentrations of ammonia were found in minewater and tailings pond liquid.* In one case where 39.85 ppm NH_3 was found in tailings dam seepage + runoff, it has to be assumed that fertilizer on the

tailings dam wall caused the very high value because liquid in the same tailings pond ran only 2.00 ppm NH_3.

REGULATED AMMONIA LIMITS IN EFFLUENT

According to the U.S. EPA (1976), the objective for ammonia in receiving waters is 0.020 mg/l as un-ionized ammonia for freshwater aquatic life.

Concentration of un-ionized ammonia varies depending on total ammonia concentration, temperature, and the pH of water according to the following tables. These firstly show the percent un-ionized ammonia in aqueous ammonia solutions and the concentration of total ammonia (NH_3 + NH_4^+) which contain an un-ionized ammonia concentration of 0.02 mg/l NH_3.

According to a NORANDA internal survey, a 1972 U.S. EPA document found that un-ionized ammonia of 400 ug/l or more may constitute a hazard to marine life while levels below 10 ug/l present minimal risk to marine biota.

The MINISTRY OF ENVIRONMENT (1979) of Ontario also set the objective of 0.02 mg/l unionized ammonia for protection of aquatic life.

It is of interest that the U.S. EPA (1981) Development Document for Effluent Limitations Guidelines and Standards for the Ore Mining and Dressing Point Source Category did not include ammonia.

-Concentrations of total ammonia (NH_3 + NH_4^+) which contain an un-ionized ammonia concentration of 0.020 mg/l NH_3(mg/l)*

Source: NWWA "Standard Methods," 16th Edition.

The South African Government Gazette (1962) Regulation No. R533 set a general effluent limit for "free and saline ammonia as 10 mg N/l and a special standard for discharges to certain listed troutbearing surface streams at 1 mg/l "free and saline ammonia" as N.

Ammonia limits set in permits for mines and mills visited in North America were often not specified or ranged from 1 to 30 ppm NH_3 expressed as N.

On February 7, 1984, the U.S. EPA published in 49 Federal Register, page 4551 and 4553, a summary of revisions to the "Guidelines for Deriving National Water Quality Criteria for the Protection of Aquatic Life and its Uses" wherein it was proposed that the "Final Acute Value" of 0.30 mg/l NH_3 derived in the "1983 Ammonia Criteria Document" should be divided by two for a criterion maximum concentration.

Motivation for this is that the final acute value (0.30 mg/l NH_3) is intended to protect 95% of a group of diverse species unless an important species is more sensitive. "However, a concentration that would severely harm 50 percent of the fifth percentile or 50 percent of a sensitive important species cannot be considered to be protective of that percentile or that species."

"Dividing the Final Acute Value by 2 is intended to result in a concentration that will not severely adversely affect too many of the organisms."

The American Mining Congress has argued that dividing the FAV for ammonia of 0.30 mg/l NH_3 by two is not clearly supported by any specific field data.

It is interesting that regulators are arguing about whether or not the maximum criterion should be 0.15 or 0.3 mg/l NH_3 as N when most permits either do not include ammonia or include it in a range from 1-30 mg NH_3/l which are 6-20 times higher than the proposed new maximum criterion.

In one case, the level must refer to the receiving stream concentration whereas, in the other, it refers to the ammonia level in the discharge stream itself.

Whereas it is not the intention of this report to review toxicity nor health effects of various contaminants, it appears that the proposed ammonia maximum level criteria will be subject to review for some time and that the proposed levels of 0.15 or 0.30 mg NH_3/l total would, if enforced, present a serious obstacle for minewater discharge from operatons that use ammonium explosives and sewage treatment plant effluents.

Ammonia in mine and mill effluents is an example of a case for, at most, site specific regulations. Since ammonia is harmful only to fish, effluent regulations on ammonia should only be applied where there is a sensitive aquatic environment to protect.

TYPICAL AMMONIA LEVELS IN DISCHARGES

Based on a casual survey of reported ammonia levels in mine/mill effluents, these range anywhere from 1 ppm to over 20 ppm NH_3. For instance, Quirke Lake in Ontario, which is part of a macro water recycling pattern serving the Elliott Lake Uranium Mines and Mills, ammonia runs around 22 ppm according to MALAIYANDI and SASTRI (1981). According to WHITLOCK and MUDDER (1984), minewater from HOMESTAKE's Lead, S.D., operations contains 5.0-6.0 mg/l NH_3 while the tailings decant runs at less than 1.0 mg NH_3/l.

ANALYSIS FOR AMMONIA

The American Water Works Associaton Handbook on "Standard Methods" is generally used as a source of analytical techniques.

WEATHERBURN (1967) described a method using phenol-hypochlorite which has been referred to in the literature.

MOTIVATION FOR AMMONIA REMOVAL

Ammonia may need to be removed from minewater or mill tailing decant water before it can be discharged as an effluent.

On the Witwatersrand, an interesting need for ammonia removal was encountered. The South African gold and uranium mines are very labor intensive and employ thousands of underground miners at each mine. These mineworkers are often housed in mine "compounds" which consume large amounts of water and are serviced by equally large sewage treatment plants. It was pointed out that a mine housing complex may well yield 2000 m^3/d of treated sewage effluent which is usually discarded to drainage.

Because of the shortage of water due to drought conditions, companies have been trying to find a way to use the treated sewage effluent to supplement mine cooling water, even possibly by spraying it into the ventilation ducts. By law, all water used underground in South African mines must be chlorinated to breakpoint as it is likely to be used for refreshment.

Because of organics present and ammonia levels, this would require excessively expensive chlorine consumption. Work is in progress to determine whether chloramines are an adequate disinfectant which would support changing the law to allow a more economical practice. Questions have been raised as to whether viruses are resistant to chloramine and the possibility of generating chlorinated organic compounds.

Some of the environmental problems associated with the various forms of nitrogen (including ammonia) are as follows:

- Nitrogen compounds are nutrients and may cause undesirable algal growths.
- NH_3 can be toxic to fish and other aquatic life.
- NH_3 and organic nitrogen in effluents can cause a dissolved oxygen demand in receiving waters.
- NH_3 is corrosive to certain metals.
- NH_3 can have detrimental effects on disinfection of water supplies.
- NO_3, an oxidation product of ammonia, can be a health hazard.

The nitrogen cycle.

METHODS FOR AMMONIA REMOVAL

Several methods are in use for removal of ammonia from effluents of various types. None of them have been applied specifically for the treatment of minewater or mill tailings decant water to the aurhor's knowledge. If ammonia must be removed from effluents, much can be learned from the sewage treatment industry. CULP, et al. (1978) provides one of the most informative descriptions of various ammonia removal processes:

- Ammonia Stripping
- Selective Ion Exchange
- Biological Nitrification-Denitrification
- Breakpoint Chlorination
- pH Change
- Desalination

Probably the best and least costly approach to ammonia removal from mill effluents is to avoid using ammonia at all. In many cases, metallurgical facilities have converted to non-ammonia systems--e.g., for elution of uranium from IX resins or for precipitation of

uranium from concentrated eluates. It is not known how economically feasible it would be for a mine to convert from ammonia-based explosives.

pH CHANGE

One example was found where ammonia was introduced to a large minewater holding pond via a small amount of sewage effluent. Due to bacterial action, CO_2 in the water was consumed which resulted in a pH increase such that the reduced ammonia limits could no longer be met. Rather than remove ammonia, it was found to be less expensive to add CO_2 to drop the pH. The table above indicates that by decreasing the pH from 9 to 6, the total ammonia level allowed without exceeding the 0.02 ppm NH_3 un-ionized limit increases from 0.070 ppm to 50 ppm.

AMMONIA STRIPPING

Ammonia stripping is described in detail by VAN VUUREN (1981) and CULP, et al. (1978).

Of the available methods for removal of nitrogen from wastewater, ammonia stripping is the simplest and easiest to control. There are two serious limitations which the designer must recognize:

1. Ammonia stripping does not work at ambient air temperatures below 32°F.

2. Calcium carbonate scale is likely to be deposited onto the stripping tower slats which results in a reduction of air circulation and droplet formation with loss of efficiency.

In warm climates, the temperature limitation does not apply, and in some locations in cold climates such as alongside a flowing river, nitrogen removal may not be required during winter. There are ways to eliminate or control scale.

Under the right climatic conditions and with provisions for scale prevention or removal, ammonia stripping is a practical, reliable method for nitrogen reduction. If nitrogen removal is necessary during freezing weather, then ammonia stripping can be used in warm weather and a supplemental method, such as ion exchange, employed during the cold seasons.

AMMONIA STRIPPING PROCESS

More than 90 percent of ammonia in most effluents is in the form of ammonia NH_3 or compounds from which ammonia is readily formed.

If certain conditions are met in the secondary treatment process of sewage, the ammonia will be converted to nitrate. CULP, et al. (1978) point out that it is cheaper to maintain the nitrogen as ammonia and to remove it in that form than to remove it as nitrate. The nitrificaton process can be eliminated by maintaining a relatively high organic loading in the secondary process.

Either ammonium ions NH_4^+, or dissolved ammonia gas NH_3, or both may be present as seen above in the tables. At pH 7, only ammonium ions in solution are present. At pH 12, only dissolved ammonia gas is present, and this gas can be liberated from wastewater under proper conditions. The equilibrium proceeds to the right at pH over 7. $NH_4^+ = NH_3 + H^+$.

Two major factors affect the rate of transfer of ammonia gas from water to the atmosphere:

1. Surface tension at air-water interface.

2. The difference in concentration of ammonia in the water and in the air.

Surface tension is at a minimum in water droplets when the surface film is being formed, and ammonia release is greatest at that instant. Little additional gas transfer takes place once a water droplet is completely formed; therefore, repeated droplet formation and coalescing of the water assists ammonia stripping.

To minimize ammonia concentration in the ambient air, rapid circulation of air is beneficial. Air agitation of the droplets may also speed up ammonia release.

The ammonia stripping process consists of:

1. Raising the pH of water to 10.8-11.5.
2. Formation and reformation of water droplets in a stripping tower.
3. Providing air-water contact and droplet agitation by circulating large quantities of air through the tower.

In designing an ammonia stripping tower, it is important to make sure that in solving a water pollution problem, an air pollution problem is not being created.

ENVIRONMENTAL FACTORS

Three potential environmental impacts need to be addressed if an ammonia stripping tower is to be proposed:

- Air Pollution
- Washout of Ammonia from the Atmosphere
- Noise

At an air flow of 500 ft^3/gal and at an ammonia concentration of 23 mg/l in tower influent, the concentration of ammonia in the stripping tower is about 6 mg/m^3. Since the odor threshold of ammonia is 35 mg/m^3, the process would not present an odor nuisance. Concentrations of 280-490 mg/m^3 can cause eye, nose, and throat irritation. 700 mg NH_3/m^3 can have an adverse effect on plants. 1700-4500 mg NH_3/m^3 or more is needed before animal or human toxicity effects start to occur.

Background levels of ammonia in the atmosphere vary from 0.001 mg/m^3 to 0.02 mg/m^3.

Concentrations of ammonia in rainfall washout approach natural background levels within about three miles of the tower. Most soils retain ammonia.

CULP, et al. point out that ammonia stripping towers can be noisy; the noise, however, can be controlled as follows:

Motors: Proper installation, maintenance and insulation.
Fans: Reduction in tip speed and installation of exhaust silencers.
Water: Shielding of the tower packing and air inlet plenum.

DESIGN

The major factors affecting design and process performance include tower configuration, pH, temperature, hydraulic loading, tower packing depth and spacing, air flow, and control of calcium carbonate scale.

There are two basic types of stripping towers now used in full scale applications: Counter current towers and crossflow towers. Counter current towers (the entire airflow enters at the bottom of the tower while water enters at the top and falls to the bottom) have been found to be most efficient. Crossflow towers have been found to be more prone to scaling.

Often pH may be high already if, for example, for phosphorus removal upstream, pH had already been raised. If not, the costs of stripping will be higher if it must be brought about solely for ammonia stripping.

CULP, et al. (1978) provide details of many useful aspects to be taken into account in designing and operating ammonia stripping towers.

Performance of 87-92% of total nitrogen removal in this way is typical.

CROSS-FLOW TOWER

COUNTERCURRENT TOWER

Source: CULP, et al. (1978)

AIR FLOW

In general, 550 cfm/ft^2 is considered to be the practical upper limit for countercurrent towers, although in warm weather conditions, 300 ft^3/gal. will give 90% removal, and 500 ft^3/gal. will achieve about 95% removal.

Typical air design quantites for 90% removal are:

Orange County, California	400 ft^3/Gal
South Lake Tahoe	390 ft^3/Gal
Pretoria, South Africa	338 ft^3/Gal

The required air quantities are usually provided by a fan located on top of the tower. Two-speed fan motors may be used. Horsepower requirements for the fans are not great for these large quantites of air at a small (say one inch) pressure drop. For the 15 mgpd Orange County plant, total installed fan brake HP is 1,380.

SCALE CONTROL

Scaling results from deposition of calcium carbonate from unstable high pH water flowing through the tower. Scaling potential can be minimized by using a high level of solids recycle in the clarification step after lime treatment. Another approach would be to eliminate the CO_2 from the air.

Portions of the tower packing on which scale is deposited are readily cleaned using high pressure hoses.

CULP, et al. (1978) mentions several different scaling experiences in actual plants. The use of a scale inhibiting polymer supplied by CALGON, NALCO, etc. also offers a means of scale control.

VAN VUUREN (1981) pointed out that environmental conditions, i.e. ambient air temperature, humidity, and the diurnal and seasonal temperature differences affect the performance of ammonia stripping. He also describes a relatively simple pilot plant. During periods of high humidity, the performance improved markedly. For example, during the Pretoria summer rainy season, removals of 90% and more were readily achieved. However, when low humidity air was used in winter at lower temperatures, the cooling effect was greater, and efficiency of the tower dropped to around 50%.

The effects of pH and temperature on the distribution of free ammonia and the ammonium ion in water.

Source: Van Vuuren (1981)

CULP, et al. (1978) also show how ammonia can be recovered from the exhaust gas if necessary.

Numerous ammonia stripping plants have been installed, and design data of a few are provided as examples:

SELECTIVE ION EXCHANGE

Conventional ion exchange resins are not selective enough to be useful for ammonia removal from water. However, clinoptilolite clay is selective for ammonia, and a process

has been developed as described by KOON and KAUFMAN (1971), BATELLE NORTHWEST (1971), and BATELLE NORTHWEST (1969).

Clinoptilolite is a zeolite which occurs naturally in several deposits in the western U.S.A., including near Hector, California. Recently, a deposit was discovered in Natal, South Africa, which is controlled by PRATLEY INDUSTRIES, Krugersdorp.

Clinoptilolite is selective for ammonium relative to calcium, magnesium, and sodium, and ammonia may be eluted from the adsorbent as well as stripped from the regenerant solution allowing both the clinoptilolite and the regenerant to be reused. Ammonium may also be recovered for reuse as fertilizer.

THE PROCESS

Wastewater is passed downward through a 4-5-foot bed of 20 x 50 mesh clinoptilolite granules until ammonia levels in the effluent exceed a desired point at which the bed is regenerated by passing a concentrated NaCl solution through the bed. Problems associated with brine disposal are overcome by removing ammonia from it rendering it suitable for reuse.

Basic ion exchange principles can be used to determine the capacity of clinoptilolite for ammonia, and BATELLE NORTHWEST (1971) provides an example of how to size a unit. CULP, et al. (1978) provide a simplified way of designing such a plant. CULP, et al. (1978) show the following comparison of the adsorption isotherm for HECTOR clinoptilolite and an ion exchange resin IR120. This shows that the favorable isotherm shape is greater than one for the clinoptilolite isotherm. Clinoptilolite is selective for ammonium relative to all common cations except potassium.

Total exchange capacity of clinoptilolite ranges from 1.6 to 2.0 meq/l. With typical cation concentrations encountered in municipal wastewaters, the capacity for NH_4^+ is around 0.4 meq/g.

NITROGEN REMOVAL

CLINOPTILOLITE

Clinoptilolite is a zeolite consisting of a hydrated silicate matrix containing alkali and alkali earth metal ions. Clinoptilolite is commonly found in bentonite deposits in the western U.S.A. The Hector, California, clinoptilolite is in the sodium form. Not all

deposits produce a material that is strong enough to be used in columns. When crushed, screened, and attrition washed to remove clay, 20 x 50 mesh Hector clinoptilolite has a five-minute wet attrition rate of three percent according to MERCER (1969). The wet 20 x 50 mesh clinoptilolite has a specific gravity of 1.59 and a bulk density of 0.74-0.79 g/cm^3.

Clays and zeolites are often unstable towards acids and alkalis. Clinoptilolite is relatively resistant to acid and caustic solution although strong caustic solutions attack clinoptilolite but not in the concentrations used for ammonia removal and regeneration.

DESIGN FACTORS

Factors affecting process efficiency include pH, hydraulic loading rate, clinoptilolite size, pretreatment, wastewater composition, and bed depth. These are discussed by CULP, et al. (1978).

Optimum ammonium exchange occurs in the pH range 4-8. Below pH 4, ions compete for loading sites; above pH 8, ammonium converts to ammonia which does not load.

7.5-20 bed volumes/hour using 20 x 50 mesh clinoptilolite (0.95-2.7 gpm/ft^2) have been used with good results. Ammonium concentrations of 0.22-0.26 ppm NH_4^+ in the effluent after contacting clinoptilolite have been reported by KOON and KAUFMANN (1971). At rates beyond 20 BV/hour, the exchange kinetics suffer, and significant ammonium leakage occurs.

Based on 20 BV/hour, a 2000 m^3/d sewage effluent treatment would require a clinoptilolite adsorption contactor with a bed volume of 4.6 m^3 allowing 10% for regeneration.

Better kinetics can be achieved with finer sized clinoptilolite, but elutration losses will be greater, and CULP, et al. (1978) recommend the use of 20 x 50 mesh adsorbent.

Head loss at 15 BV/hour in a three feet deep bed (5.6 gpm/ft^2) is calculated at 2.1 feet with 20 x 50# adsorbent. A six-foot bed under the same circumstances would result in a head loss of 4.2 feet.

Bed depths of six feet were generally more efficient than three-feet depth at the same number of bed volumes/hour because the upflow velocity is much less for a three foot bed than a six foot bed, and at the lower velocity in a three-foot bed, some plugging may occur which reduces the efficiency. Full scale designs are reported to use four foot bed depths with a high degree of pretreatment (coagulation and filtration).

MULTIPLE COLUMNS VS. SINGLE COLUMN

The number of bed volumes treated per cycle can be increased with the same effluent quality using two or more columns in series according to standard ion exchange practice. Tests indicated that ammonium loadings can be increasd from 55 -58 percent of equilibrium capacity to 85% by using two columns in series, and average inputs at the Tahoe plant were increased from 150 to 250 BV/cycle. Because of added capital costs in a series system, all commercial-scale units up to 1978, anyway, used parallel single beds. Improved utilization of available exchange capacity was achieved by blending effluents from several parallel columns, each in a different stage of exhaustion.

To avoid excessive headloss, feedwater should have less than 35 mg/l suspended solids, and no problems are anticipated with organic fouling because biological growth is adequately removed during salt regeneration.

CULP, et al. (1978) report results of pilot tests for ammonia removal from three wastewaters with 12-16 ppm NH_4^+-N, and there was a marginal increase in bed volumes to 50% breakthrough point for feedwaters containing lower competing ion concentrations, e.g., about 10-25% greater. The 50% breakthrough point was reached typically after 300-400 BV.

Breakthrough curves for a single six-foot column of clinoptilolite operated at 6.5-9.7 BV/hour with 15-17 ppm NH_4^+-N in the feed stream indicate that about 150 BV could be used for design purposes for effluents requiring less than 2 ppm NH_4^+-N. Although the effluent, after 150 BV, is around 2 ppm NH_4^+, the average effluent to this point in the cycle is less than 1 mg/l.

Breakpoint chlorination would be more economical for removal of residual ammonia below 1 ppm NH_4^+-N, especially if the water is to be desinfected with chlorine anyway.

DETERMINATION OF IX CONTACTOR SIZE

Determination of the contactor size is found by testing the clinoptilolite capacity for ammonium adsorption from the characteristics of the feedwater which can be determined experimentally or estimated from a table provided in CULP, et al. (1978), page 334, if the ionic strength of the feedwater is known.

REGENERATION ALTERNATIVES

Using concentrated salt solution to regenerate the clinoptilolite loaded to breakthrough, the volume of ammonium laden, spent regenerant is about 2.5-5 percent of the throughput

treated prior to regeneration. By removing ammonium from the spent regenerant, regenerant can be recycled for reuse. Alternative ways to recover regenerant are:

Air Stripping
Steam Stripping
Electrolytic Treatment

Regeneration is in an upflow mode.

HIGH pH STRIPPING

Use a 5 g/l lime slurry to which 0.1N NaCl has been added. The volume of regenerant needed decreases with increasing pH, and the ammonium is converted to ammonia ready for removal from the regenerant.

High pH regeneration, however, leads to precipitation of magnesium hydroxide and calcium carbonate during the regeneration cycle which plugs the exchanger inlets and outlets and fouls the zeolite particules. This is overcome by using neutral regeneration in a closed loop.

NEUTRAL pH REGENERATION

The 15 mgd Upper Occoquan regional plant in Virginia and the 6 mgd Tahoe-Truckee Sanitation Agency plants in California use a regenerant near neutral pH. The regenerant consists of two percent NaCl requiring 25-30 BV to reach equilibrium at a typical rate of 10 BV/hour. Provision is made for backwash at 8 gpm/ft^2 and a surface wash of the contactor prior to initiation of regenerant flow.

Air stripping of high pH regenerant removes ammonia from it until the NH_3-N is reduced to around 10 mg/l. Liquid flow rate to the stripper was typically 2 gpm/ft^2 with an air-liquid ratio of 150 ft^3/gal in a pilot plant. Severe scaling resulted which required overdesign in the commercial plant.

Air stripping of neutral pH regenerant containing two percent NaCl at near neutral pH solved the scaling problem in the zeolite contactor.

Ammonia can be recovered by passing the gases through an absorption tower containing sulfuric acid. Some detail of possible arrangements is provided by CULP, et al. (1978)

A typical elution curve after U.S. EPA (1975) is shown:

Stream stripping of ammonia to recover the regenerant is economical only for high pH regeneration and is used at the Rosemont, Minnesota plant.

A third alternative is to use electrolysis to generate chlorine from the salt in the regenerant at neutral pH which converts ammonia to nitrogen and hydrogen after soda ash treatment for calcium removal. Pilot tests indicate a consumption of 50 watt-hours per gram of ammonia or 4.7 kWh/1,000 gallons. Electricity required for air stripping is only about 10% of that for the electrolytic process.

OPERATING PLANT PARAMETERS

Operating parameters and performance data for two U.S. plants is provided in CULP, et al. (1978) for the Rosemont plant in Virginia reported by U.S. EPA (1975). Typical ammonia removal efficiencies are 90 percent at 10°C and 95% at 20°C which indicates the efficiency of this process.

It is known that work on the use of clinoptilolite ammonia removal is being undertaken in South Africa by:

BIOLOLGICAL REMOVAL OF AMMONIA AND NITRATES

Nitrogen may be removed both as ammonia (nitrification) and as nitrogen (denitrification). Nitrification of ammonia takes place in a controlled aerobic environment, and denitrification takes place if the nitrified effluent is subjected to a period of anaerobiosis to allow saprophytic bacteria to utilize the nitrates as electron acceptors.

Nitrification and denitrification require simple equipment, and no liquid or solid by-products are created.

All of the biological system designs for nitrogen removal are based on a sequence of: 1) oxidation of carbonaceous materials; 2) oxidation of nitrogenous materials including ammonia; and 3) reduction of nitrates.

Nitrification is carried out by two groups of autotrophic bacteria, Nitrosomonas and Nirobacter, which must operate sequentially because Nitrosomonas can oxidize ammonia to nitrite, and Nitrobacter is limited to oxidation of nitrite to nitrate.

Nitrification processes fall into several categories:

Single stage in which the carbonaceous and nitrogenous oxidation steps are combined in a single reactor rather than first achieving the carbonaceous oxidation in a separate reactor.

Suspended growth - nitrification in a mixed reactor such as a conventional aerated tank.

Attached growth nitrification is accomplished by organisms attached to a growth media as in a trickling filter or rotating biological contactor (RBC).

Both suspended and attached growth systems are used for denitrification.

Several factors are important in the nitrification process and the design of a plant.

pH - pH should be somewhere around pH 8.0-8.5 to achieve a maximum nitrification rate. Acid pH will depress the rate of nitrification although acclimation is possible to pH 5.5. The nitrification process itself can depress the pH below optimum levels:

$$NH_4^+ + 2O_2 + 2HCO_3^- \rightarrow NO_3^- + 2H_2CO_3 + H_2O$$

7.14 mg of alkalinity (as $CaCO_3$) is destroyed per mg NH_4^+ nitrogen oxidized.

Temperature has a marked influence on nitrification attached growth systems; e.g., on an RBC, it can compensate for colder temperatures by accumulating thicker slime growths.

Dissolved oxygen - increased dissolved oxygen concentration greatly enhances the rate of nitrification, and the efficency of the air diffusion system has a marked impact on nitrification performance.

Ammonia concentration has little effect on the rate of nitrification until a level of 2.5 mg NH_4^+-N is reached below which the rate of nitrification decreases sharply.

Toxicity - several heavy metals, complex anions, and organic compounds are toxic to nitrification organisms, but a degree of accumulation is possible. Some of the toxins include:

Thiourea	
Zn	Cr
OCN^-	Ni
ClO_4^-	Ag
Cu	Thiourea
Hg	Amino Acids

Apparently, 10-20 mg/l of heavy metals can be tolerated because of low ionic concentrations at pH 7.5-8.0, but if precipitated metals that concentrate in the sludge should redissolve if the pH should fall, then the system could fail. High concentrations of ammonia or nitrite are also toxic to the nitrification process.

NITRIFICATION BY ATTACHED GROWTH SYSTEMS

Rock Trickling Filters

Nitrification is usually achieved only at low hydraulic loading rates and warm temperatures, and nitrification is difficult to maintain in a conventional rock trickling filter. Significant nitrification will not occur at loading rates in excess of 12 lb. BOD/1000 ft^3/day. Synthetic media is more effective for denitrification, partly because the surface area of synthetic media at 27 ft^2/ft^3 is about double that of 3" rock at 12-18 ft^2/ft^3.

Synthetic Media Trickling Filters

Combined carbon oxidation and nitrification can be achieved in a single-stage system using synthetic media towers. BOD loading is again the limiting factor which should not exceed 25 lb/1,000 ft^3/day.

Recycling is necessary to prevent the media from drying out, and this requires 0.5-1.0 gpm/ft^2. Recycling is also important to maintain a uniform flowrate.

Rotating Biological Contactors (RBC's)

RBC's may be used for single stage or two stage nitrification systems. These equipment items consist of a series of closely spaced discs (10-12 mØ) mounted on a rotating horizontal shaft with about 50% of their surface area immersed in wastewater. The discs are constructed of lightweight plastic, and, in operation, are covered by a 1/16-1/8 inch layer of biological slime. A very large surface area is packed into a small volume in RBC's which serve two purposes. First, they provide media for the growth of attached microbial growth, and they contact the growth with the water. Secondly, they aerate the water and agitate the suspended biomass in the wastewater resevior. Rotation speed is adjustable, and one company, ENVIROX DIVISION OF REXNORD, now makes a unit which is rotated by air that collects in cup-shaped collectors on the outside edge of the discs which seems to work particularly well.

RBC's can be used in series for nitrification followed by denitrification.

Submerged Filters

Submerged filters have been applied for nitrification. These consist of a bed of media on which biological growth occurs overlaying an inlet chamber with feedwater flowing upwards. Rather large detention times of, say, 60 minutes at 15°C are needed to denitrify 20 mg/l NH_3-N. Various ways have been devised to add air to the system. Preoxygenation produces effluents of similar quality to those from tertiary multi-media filtration.

Activated Biofilters

The activated biofilter (ABF) process operates as a two-stage biological system which includes the following components:

1. Pump to lift return sludge plus influent feed to the top of the fixed film bio-cell.
2. A fixed film bio-reactor.
3. Flow control and splitting.
4. A short detention aeration basin.
5. Clarifier.
6. Return sludge facilities.

ENHANCED RATE BIOLOGICAL CONTACTOR

FLUID BED NITRIFICATION

The National Institute for Water Research of the CSIR, Pretoria, is involved in a paper study on how best to remove 20 mg NH_3/l in reclaimed water which would be a source of water for the large refrigeration plants on South African gold and uranium mines.

One possibility under consideration is the development of an upflow fluidized bed of sand to provide an activated sludge with media support for Nitrobacter pseudomonas. An organic source would be provided in the form of molasses or sewage sludge. The upflow fluid bed configuration was expected to give a tenfold rate increase.

Subsequent studies had indicated that the corrosion effects of ammonia at 20 mg/l were not very serious on the refrigeration tubes. Also, FLOCCATAN (PTY) LTD., the local subsidiary of CALGON CORP., can supply additives that would protect the copper/brass cooling tubes from ammonia corrosion.

Design criteria for biological ammonia removal processes are beyond the scope of this report but can be provided by any one of several leading municipal water treatment specialists.

For most mine and mill effluents, the conventional ammonia removal processes used in sewage treatment plants for tertiary treatment are unlikely to be applicable because of the lack of adequate organic cometabolites. Several sources of organic material could be investigated:

- Molasses
- Sewage
- Harvested Cattails and Other Marsh Plants

ALKALINE CHLORINATION

Ammonia can be destroyed chemically by chlorination. The initial reaction is the formation of chloramine, and, until all chloramine has been oxidized, no free residual chlorine is detected.

$$NH_3 + Cl_2 = NH_2Cl + HCl$$
$$2NH_3 + 3Cl_2 = N2 + 6HCl$$

Stoichiometrically, about 7 g Cl_2 is needed to oxidize 1g NH_3 to breakpoint, the point at which residual chlorine can be detected. Typical Witwatersrand treated sewage effluents, for example, require 10-12 g Cl_2 per g NH_3, and, according to NALCO (1979), ammonia

cannot always be destroyed in this fashion since many wastewaters contain organic materials that react with ammonia in preference to ammonia.

Chlorine gas reacts with water to form hypochlorous acid and hypochlorite:

$$Cl_2 + H_2O = HOCl + H^+ + Cl^-$$
$$HOCl = H^+ + OCl^-$$

The distribution of hypochlorous acid HOCl and hypochlorite OCl^- varies with pH, and at pH 7.5, about 50% of the chlorine is in the form of HOCl and 50% in the form of OCl^-. As pH increases, the OCl^- concentration increases as HOCl decreases.

Ammonia reacts with hypochlorous acid in dilute aqueous solution to form chloramines:

$$NH_4 + HOCl = NH_2Cl \text{ (monochloramine)} + H_2) + H^+$$
$$H2Cl + HOCl = NHCl_2 \text{ (dichloramine)} + H_2O$$
$$HCl_2 + HOCl = NCl_3 \text{ (trichloramine)} + H_2O$$

Chlorine (Cl_2), hypochlorous acid (HOCl), and hypochlorite ions (OCl^-) are referred to as free chlorine residual, and the chloramines are called combined chlorine residual.

The combined chlorine residual increases as chlorine is added up to a mol ration of 1:1 (weight ratio 5 Cl_2:1 NH_4-N) shown as point A. Additions of chlorine above 5 mg/l per mg/l NH_4-N result in a decrease in the chlorine residual to a minimum, the "breakpoint" at a mole ration of about 1.5:1 (weight ration 7.6 Cl_2:1 NH_4-N) indicated as point B. At the breakpoint, all oxidizing chlorine is reduced, and all ammonia is oxidized. Further additions of Cl_2 result in free chlorine residuals.

Typical breakpoint chlorination curve.

The actual mechanism and reactions that occur during breakpoint chlorination of ammonia are not clearly understood, and some conclusions arrived at by PRESSLEY, et al. (1972) and PRESSLEY, et al. (1973) include:

1. Chlorine demand to reach breakpoint decreased and approached the stoichiometric amount for oxidation of NH_4^+ to N_2 (7.6:1) as the degree of wastewater pretreatment increased.

Cl_2:NH_4-N Wt. Ratio Required to Reach Breakpoint	Wastewater Source
10:1	Raw
9:1	Secondary Effluent
8:1	Lime Clarified and Filtered Secondary Effluent

2. Alkalinity of the wastewaters maintained the pH between pH 6.5-7.5. Concentrations of nitrate and nitrogen trichloride in this pH range were always less than 1 mg/l. Near complete removal of NH_4-N was obtained with only a slight reduction of organic nitrogen within two hours contact time.

3. Highly treated wastewater exhibited breakpoint performance similar to synthetic buffered waters.

EPA studies on synthetic waters (with 20 mg NH_4-N/l) have been reported by CULP, et al. (1978) to have shown the following:

- Breakpoint reaction was complete within one minute in the pH range 6-8.

- Minimum chlorine dosage required to reach breakpoint occurred in the pH range 6-7.

- The amount of nitrate produced at the breakpoint increased from about 1.5% of the NH_4-N at pH 5 to about 10% at pH 8.

- The amount of nitrogen trichloride produced at the breakpoint decreased from approximately 1.5 percent of the NH_4-N at pH 5 to about 0.25% at pH 8.

- Temperature variation of 5-40°C at pH 6.0 and two hours contact time did not change the required chlorine dose or the amounts of the products.

Two other factors need to be taken into account:

1) Use of Cl_2 produces acid. Oxidaton of one mole of NH_4-N produces four moles H^+. Stoichiometrically, it requires 14.3 g bicarbonate alkalinity (as $CaCO_3$) to neutralize the acid produced during oxidation of 1 g NH_4-N.

2) Chloride ion concentrations increase by at least 7.6 g Cl^- for each g NH_3 oxidized.

Sodium hypochlorite can be used in the breakpoint process instead of Cl_2 gas. Reaction of sodium hypochlorite in water will tend to raise the pH instead of lowering it:

$$NaOCl + H_2O = HOCl + Na^+ + OH^-$$

The breakpoint reaction with sodium hypochlorite is represented as:

$$1.5\ NaOCl + NH_4^+ = 0.5\ N_2 + 1.5\ NaCl + 1.5\ H_2O + H^+$$

Stoichiometrically, it requires 3.6 g bicarbonite alkalinity (as $CaCO_3$) to neutralize the acid formed during breakpoint chlorination of 1 g NH_4-N with NaOCl.

CULP, et al. (1978) provides ten pages of data on nitrogen removal capital and operating costs which were based, however, on 1978 U.S.A. parameters. These, however, provide some sort of relative idea of costs and are summarized below.

Comparative Costs (Capital, Operation and Maintenance) of Alternative Nitrogen Removal Processes. (¢/1000 gal)

	1 mgd			5 mgd			10 mgd		
	10 mg/l[a]	20 mg/l	30 mg/l	10 mg/l	20 mg/l	30 mg/l	10 mg/l	20 mg/l	30 mg/l

BADENPHO AND PHOREDOX PROCESSES

The National Institute for Water Research, CSIR, Pretoria, has been developing a multi-stage phosphorous/nitrogen removal process for use in treatment of sewage effluents. These are integrated processes and would not be applicable for insertion at the end of a minewater or mill tailings decant stream for nitrogen removal.

However, where the intention is to convert a treated sewage effluent into a useful source of water for use in metallurgical processes, and/or for recycling and reuse for domestic purposes, and/or for discharge as an effluent meeting the NH_4-N and phosphorous limits, possibly these processes applied at the mine community sewage plant will solve both the problem of phosphate and nitrogen removal. The Kloof Gold Mining Co. Ltd. on the Witwatersrand sewage plant effluent has maximum 0.5 mg/l NH_4-N. It is possible that the Badenpho process is employed there, but this was not confirmed.

Description of these five-stage processes is beyond the scope of this report, but details are available from the National Institute for Water Research at the address shown above.

CHAPTER 28

ANTIMONY Sb

Antimony is not a common problem in the operations visited either from an environmental point of view or from a process efficiency standpoint.

During the course of this investigation the only operations where provision has been made for antimony removal that can be recalled are the new gold recovery operations at Hemlo, Ontario, of NORANDA MINES LTD. and LAC MINERALS. It is mentioned in the chapter on Water Management in Gold and Silver Recovery, below, and at EQUITY SILVER MINES LTD., British Columbia.

This investigation did not take into account any antimony mines, mills, and mineral processing operations. Antimony seems to be a non-problem.

REGULATORY LIMITS

No regulatory limits exist for antimony in fresh or saltwater effluents.

ENVIRONMENTAL AND HEALTH EFFECTS OF ANTIMONY

Test data is very limited, but the U.S. EPA (1980) and ANDERSON (1950) found acute toxicity for Daphnia magna, which is a commonly used test organism because of its important role in the food cycle of fish larvae, to range from 9,000 to 19,800 ug/l as Sb. Chronic toxicity for Daphnia magna was found at 5,400 ug/l Sb.

Tests with fathead minnows (Pimephales promelas) using antimony trioxide in an embryo-larval toxicity test indicated that the highest concentration tested (7.5 ug/l) had no adverse effects and in a comparable test with antimony trichloride, a chronic limit of 1,600 ug/l was established for fathead minnows (U.S. EPA, 1980).

A 96-h LC50 for the sheepshead minnows (Cyprinodon variegatus) was between 6,200-8,300 ug/l with no lethal effects at 4,200 ug/l Sb on the myrid shrimp Mysidopsis bahea after 96 hours exposure (U.S. EPA, 1980).

It is concluded that:

1. Insufficient data on antimony toxicity is available to establish water quality criteria for the protection of aquatic organisms.

56 (ug/L) ANTIMONY

2. Acute toxicity in freshwater occurs at 9,000 ug/l and could occur at lower levels for aquatic species.

3. Chronic toxicity has been recorded at 1,600 ug/l, and some species may be more sensitive.

4. At levels in which antimony is most likely to be encountered in effluent receiving waters, it appears that antimony in mine and mill effluents is rarely of potential environmental concern.

5. Toxicity to freshwater algae at 610 ug/l has been noted in U.S. EPA, (1980), indicating that antimony levels may bear watching as an influence in biological polishing systems which include the use of algae.

OCCURRENCE OF ANTIMONY IN MINING AND MILLING WASTES

Antimony occurs as the antimony sulfide mineral stibnite in Hemlo gold ores at a level of about 0.02% Sb. Stibnite and sulfosalts containing antimony in association with silver and gold and base metals are not uncommon in "refractory" gold ores, and frequently antimony minerals occur in flotation concentrates that previously were roasted. During the roasting step, antimony and lead, if present, form glasslike compounds in the calcine which can interfere with the roaster bed and also are often blamed for gold losses in the subsequent leaching step.

Gold concentrates shipped to the government roasting plant at Kwekwe, Zimbabwe, frequently contain high levels of antimony for which a severe penalty is applied.

It is not yet known how antimony will affect gold recovery from refractory ores and concentrates by pressure oxidation or bio-oxidation processes currently being developed in preference to roasting ahead of cyanidation. Although antimony occurs in ore at HOMESTAKE's new McLaughlin mine, it is not listed as an element of interest in their operating permits.

Even at EQUITY SILVER MINES LTD., where the flotation concentrates before pressure leaching to remove antimony typically ran 0.16% in the Southern Tailing ore zone and 7.11% Sb in the concentrate, the acid mine drainage contains less than 0.1 ppm Sb before treatment.

REMOVAL OF ANTIMONY

Antimony occurred in the Southern Tail ore deposit at a concentration of 0.158% and concentrated up to 7.11% Sb leaving 0.035% in the tailing. The concentrate was leached in hot caustic soda and NaHS to reduce the Sb level in the concentrate to below 0.3% Sb.

The leach liquor is filtered off the concentrate solids and the antimony recovered as sodium antimonate by an autoclave reaction for 1/2 hour at 150°C and 80 psi O_2 after which the solution is cooled in a flash tank at which point it contains about 8% sodium antimonate which is filtered on a belt filter with two stages of washing. The filtrate contains arsenic in a caustic thiosulfate solution. Sodium antimonate recovered in this way is sold as a by-product. More information is available in RANDOL (1983) and from:

EQUITY SILVER MINES LTD.
Houston, B.C.
(604) 845-7799
P. Brad Marchant

NORANDA MINES LTD. - HEMLO

The Hemlo gold ore is rich in pyrite and contains relatively large and variable amounts of environmentally undesirable metals. The average composition of Hemlo ore is approximately:

Gold	4-16 g Au/t
Silver	0-2%
Mercury	16 g Hg/t as Cinnabar
Molybdenum	0.03-0.04% MoS_2
Zinc	0.002% Sphalerite
Antimony	0.02% Stibnite
Arsenic	0.02% as Realgar

The metallurgical gold recovery circuit using straight-forward cyanidation has had to take into account ore characteristics as well as a very sensitive location adjacent to a provincial park on one side and an Indian fishing ground on the other.

Water management for the operation has required an integrated plan including a partially-lined tailings pond with seepage collection and return, mine backfill, tailings treatment to remove molybdenite with some of the arsenic, mercury, and antimony sulfides and finally, effluent treatment for cyanide and residual soluble antimony and arsenic removal. The effluent treatment plant flow diagram and how it fits into the overall mine-mill-tailings arrangement is shown in the following diagrams.

Noranda Mines Limited
Hemlo Project Deposit No.1
Effluent Treatment Plant
Flow Diagram

Noranda Mines Limited
Hemlo Project Deposit No.1
Overall Water Balance
Figure 6-1

1990

The addition of lime and ferrous sulfate to the effluent o/f after SO_2-Air cyanide destruction, metal precipitation, and thickening is projected to drop the soluble antimony level from 1-30 ppm (average 10 ppm) Sb to around 2.0 ppm. Antimony removal from the effluent is likely to be less of a concern than removal of metals such as mercury, copper, and arsenic.

Additonal information on the Hemlo effluent treatment process is available in NORANDA (1983) and from NORANDA MINES LTD. LAKEFIELD RESEARCH carried out the Hemlo effluent treatment testwork and may be free to discuss antimony removal processes.

LAC MINERALS, HEMLO PROJECT

LAC MINERALS is developing a gold mine and mill at Hemlo, Ontario. No information on precisely how LAC MINERALS plans to treat their effluent or even the composition of their ore was obtained, although it is possible that it will contain a similar suite of undesirable contaminants.

It is believed that GOLDER ASSOCIATES has been responsible for the overall water management investigation for this project:

GOLDER ASSOCIATES LTD.
Mississauga, Ontario
(416) 625-0094
Don Welch
George Costa

It is also believed that testwork to evaluate effluent treatment processes for LAC MINERALS' Hemlo project has been carried out by WITTECK DEVELOPMENT, INC. which is one of the first test programs for a gold extraction plant that takes into account the effects of water recycling on water quality and metallurgical efficiency.

CONCLUSIONS

1. In some parts of the world effluent discharge regulations with respect to arsenic are extremely tight whereas in others, they are lax. Much more knowledge is needed about the toxicology and health effects of different arsenic species.

2. Arsenic can be removed readily from solutions down to relatively low levels provided it is oxidized to arsenic (+5) and that appropriate cations are present to make an insoluble precipitate.

3. Sludge stability is of concern as there is evidence that some precipitates resolubilize when they come into long-term contact with CO_2 from the atmosphere.

4. Arsenic control in the environment around mine-mill effluents requires an integrated program covering all aspects of mine-mill-roaster-tailings management.

5. The answer to long term stability of arsenic-bearing sludges lie in sludge disposal and stabilization or in making a more stable precipitate in the first place.

INTRODUCTION

Arsenic removal is important because of its acute toxicity not only to aquatic life but also to humans. Review of present day disposal methods may be needed because of questions as to the long-term stability of arsenic precipitate sludges.

Arsenic is a metal which forms toxic oxides, principally trivalent arsenite AsO_2^- and pentavalent Arsenate AsO_4^{-3}. The less stable arsenite is significantly more toxic to fish than pentavalent arsenic in arsenate. The oxidation state of the anion is believed to have a significant impact on the efficiency of processes to remove arsenic from solutions according to PATTERSON (1975).

Arsenic, like cyanide, enjoys an unfair degree of public and regulator paranoia compared with other contaminants from the mining and metallurgical industry.

OCCURRENCE OF ARSENIC IN THE ENVIRONMENT

Arsenic occurs in nature in deposits of arsenopyrite and sulfosalts in mineral deposits where it is commonly associated with iron, sulfur, antimony, silver, cobalt, nickel, and other base metals minerals. Natural weathering of rocks containing these minerals results in arsenic distribution to soils and groundwater in affected regions. Several plants are known to concentrate arsenic, and sporadic groundwater aquifers occur

which are contaminated by arsenic to the extent that they are unusable--mostly in the western states.

High arsenic levels have been encountered in few municipal water supplies necessitating treatment for its removal. Many groundwater supplies in Central and South America contain excessive arsenic according to TRELLES and ARMATO (1950) and VINIEGRA and MARQUEZ (1965), and deep-well water in some desert areas in the U.S.A. contain in excess of 0.1 mg/l arsenic (BELLACK, 1972).

Arsenic in the form of arsenical compounds occurs in the wastewaters of the metallurgical industry, glassware and ceramic production, tanneries, dye, and pesticide manufacture. Other sources include the organic and inorganic chemicals and petroleum refining industry and the rare-earth industry (SKRIPACH, 1971). The manufacture of Paris Green and calcium-metaarsenate, both insecticides, in one instance produced a wastewater containing 362 mg As_2O_3/l according to CHERINSKI (1941). In recent years (PATTERSON, 1975), with the development of organo-arsenic compounds, many arsenic-based forms have declined in use. During the 1980's there has been a significant increase in the demand for arsenic oxide feed material, and this may to some extent be the result of the expanded use of an arsenic wood-preserving process--the one with a green finish. It is also used in hide preservatives, sheep dip, glass manufacturing, and electronic components.

In the mining industry, arsenopyrite is frequently associated with gold deposits in several gold belts of the world. Notable arsenopyrite gold regions include Kalgoorlie, Western Australia; the Ashanti Goldfields, Ghana; the Emperor Gold Mine, Fiji; several mines on the Canadian Shield including Campbell Red Lake, Giant Yellowknife and early CON operations in the Northwest Territories; the Barberton Gold Belt of the Eastern Transvaal; several mines in Zimbabwe including Dalny and the now exhausted Cam and Motor Mine; the Getchells deposit in Nevada; and several deposits in the Soviet Union as well as the Salsigne deposit in France. There are many more less famous arsenical gold occurrences in the world, and arsenic frequently occurs in small amounts in many non-refactory gold ores.

Arsenic sulfosalts occur with copper and silver sulfides at the Equity Silver Mine in British Columbia and with copper-gold concentrates at the El Indio Mine in Chile. Arsenic also occurs with cobalt in sulfide ores at sites such as the Blackbird Mine in Idaho and at Cobalt, Ontario, where cobalt and arsenic have been liberated by pressure oxidation.

Arsenic also occurs in lesser amounts with copper-lead-zinc ores and concentrates and becomes concentrated in roaster and smelter fluedusts often increasing in concentration due to recycling of dusts and water used in gas scrubbers. One such case is a lead smelter in Canada, where arsenic enters the system primarily with lead-bearing fluedusts.

Considering the price of lead and the cost of freight, the economics in today's economy of the use of some fluedusts in this way compared with pozzolonic disposal nearer the source of the fluedust is probably favorable in special cases only.

Arsenic also occurs in some uranium deposits, particularly the high grade deposits in Saskatchewan where is must be precipitated from effluents as at Key Lake.

REGULATORY EFFLUENT DISCHARGE CRITERIA AND LIMITS

Criteria

Fresh Water:

U.S. EPA, (1980)	440 ug/l	As^{3+} Maximum Permissable Concentration
Canada, (1979)	50 ug/l	Total As
Ontario, (1979)	100 ug/l	Total As Maximum Permissable Concentration
Quebec, (1977-80)	10 ug/l	Total As Minimum Permissable Concentration
South Africa, (1962)		
Special Standard	100 ug/l	Total As
General Standard	500 ug/l	Total As

Marine:

U.S. EPA, (1980)	Less than 508 ug/l As^{3+} may be harmful.

Public Water Supply:

U.S.A., (1980)	2.2×10^{-2} to 10^{-4} mg/l Maximum Permissable Level
Canada, (1979)	50 ug/l
Ontario, (1979)	50 ug/l
Alberta, (1977)	10 ug/l
South Africa, (1971)	
Recommended	50 ug/l
Maximum Allowable	50 ug/l

Typical total arsenic levels in effluents from mining and metallurgical operation permits range from 2 to 800 ug/l maximum average up to 160 ug/l maximum grab sample.

	Average	Maximum Daily
HOMESTAKE, McLaughlin NPDES (Zero Discharge)	0.05 ppm	0.10 ppm
Mount Emmons (Zinc)		0.05 ppm
KEY LAKE MINING	0.50 ppm	1.00 ppm
HOMESTAKE, Lead NPDES	0.38 ppm	
Cominco, Con Mine, Yellowknife, NW	0.50 ppm	1.0 ppm

	ARSENIC	
	Average	Maximum Daily
Giant Yellowknife, Yellowknife, NWT	0.80 ppm	1.60 ppm
ST. JOE, Monaca, Pennsylvania, Zinc Refinery	0.05 ppm	
NORANDA Grey Eagle, Californa Gold Mine (Zero Discharge)		0.002 ppm

It is concluded that:

1. Some discharge permits are well in excess of levels recommended as maximum to avoid damage to aquatic species.

2. Some regulations are excessively strict and were formulated on an unfirm scientific basis.

3. Permit requirements--e.g., for NORANDA Grey Eagle in California which is a zero discharge operation with a permit to dispose of excess water by irrigation--2 ppb As are ludicrous and might appear to be bureaucratic harrassment.

4. Arsenic discharge limitations for new operations in third world countries, e.g., Brazil, range from 0.1 to 0.2 mg/l depending on the state. It is expected that with maturity, the more developed countries may relax some excessively low-level arsenic requirements (e.g., 2 ppb) and that the third world countries, some of which are still lax and have just recently "discovered" environmental concerns, may first have to go through a similar phase of excessive overcompensation before they too mature.

Of interest in the PEDCO (1983) report are analyses of tailings pond solids and liquids as well as mine water pond liquid and settled solids for a wide range of mines in the U.S.A. The arsenic analyses are summarized in the table below.

It is observed that, in general, arsenic levels are low in these liquids, i.e., effluents and reclaimable recycle tailings water.

Also of interest is the fact that even where solids contain relatively high arsenic values either in settled tailings, wasterock, or minewater pond settled solids, the level of acetic acid-soluble arsenic and water-soluble arsenic is very low. Consider the following data for gold and silver mines tested by PEDCO (1983).

ARSENIC IN GOLD AND SILVER MINE AND MILL WASTE (mg/l OR ug/g)

	Waste (ug/g or mg/l)	Acetic Acid Leach U.S. EPA EP Test	Water Extract

ANALYSIS OF ARSENIC

Arsenic can be determined down to 0.002 ppm by atomic absorption spectrometry using hydride generation according to the EPA (1982), page 150.

A colorimetric method based on a color reaction with silver di-ethyl carbamate is reported to provide a detection limit of 1 ppb (0.001 ppm) and is described by AWWA 'Standard Methods.' This method is used routinely by Giant Yellowknife Mines, Yellowknife, NWT, with good results. Interferences are listed as Cr, Co, Cu, Hg, Mo, Ni, Pt, and Ag which supposedly interfere with the arsine generation step in the method, and the presence of antimony can also give a high reading because it too gives a red color reaction.

ENVIRONMENTAL AND HEALTH EFFECTS OF ARSENIC

Arsenic has for some time been a suspected carcinogen.

According to ROBINS (1984, personal communication), a population survey around the former Tacoma smelter indicated a correlation to lung cancer. On the other hand, intensive studies by the Canadian government into possible health effects of arsenic in Yellowknife, NWT, and other mining camps where arsenopyrite is roasted were inconclusive and showed no such evidence.

The environmental impact of arsenic was discussed at an international arsenic conference believed to have been held in the early 1980's in North America, but this document is not reviewed as health and environmental effects are not a focus of this investigation.

U.S. EPA (1980) and FERGUSON and GAVIS (1972) conclude that soluble inorganic arsenate (+5) predominates under normal conditions as it is thermodynamically more stable than arsenite (+3).

It has been pointed out by M. R. Speyer and L. Trudel of NORANDA RESEARCH that the majority of scientific papers on the environmental effects of arsenic are based on research conducted with arsenic in the (+3) form, and the EPA criteria are stated in terms of total recoverable trivalent inorganic arsenic.

Oysters are said to concentrate arsenic (a factor of 350 over a 112-day exposure period in one case) although it is believed that once metabolized, "organic arsenic" is not toxic to humans.

There is evidence that the LC_{50} bioassay test for marine fish ranged from 508 ug/l to 16,000 ug/l.

Trivalent arsenic is much more toxic than pentavalent arsenic, and it appears that most arsenic toxicity tests were based on trivalent arsenic. NORANDA RESEARCH found a 96-hour LC_{50} of 220,000-380,000 ug As^{V}/l for Atlantic Salmon. Even EPA (1980) data for a 96-hour LC_{50} test on Rainbow Trout for sodium arsenate of 10,800 ug/l turned out to have been performed with sodium arsenite according to HALE (1977).

It is reputed that after the Cam and Motor Mine arsenopyrite roaster shut down, health effects ascribed to the reduction of arsenic levels appeared. One possible explanation of this unconfirmed observation is that people living near the roaster had lost their immunity to certain bacteria that were killed by the high arsenic levels in the environment while the roaster operated.

Deep well waters in Taiwan containing up to 2.0 mg/l arsenic are believed to be the cause of an endemic illness called "black foot" disease and described by SHEN and CHEN (1964) and SHEN (1973).

ARSENIC FROM THE GOLD MINING INDUSTRY

Arsenic control at gold recovery operations can be generally divided into two categories--those where there is a high level of arsenic present as in arsenopyrite ores, and those where levels of arsenic in the ore are in trace amounts only.

ARSENOPYRITE GOLD ORES

By far the greatest source of arsenic in wastes that require management are generated by the roasting of refractory arsenopyrite gold ores.

The finely-ground ore is conventionally floated to yield an auriferous sulfide concentrate which is then roasted to make the gold amenable to cyanidation from the calcine. A two-stage roast is usually used in which arsenic is volatilized as an oxide and collected in varying degrees of efficiency from the roaster gas stream. The hot calcine is quenched in water and washed to remove unwanted base metals, including some residual arsenic, prior to cyanidation.

Arsenic enters the mine-mill water effluent system through several pathways:

1. Calcine washwater.

2. Drainage from the smelter area which can be contaminated by fallout from the roaster gasses.

3. Acid mine drainage from underground workings.

4. Seepage and runoff from mill tailings and wasterock.

5. Seepage and drainage from flue dust and leached calcine impoundments.

6. Leachate from calcine washwater precipitate sludges.

Historically, arsenical gold concentrates were roasted with minimal concern for arsenic removal from the roaster gases or effluents. Some of these have been in operation for half a century, and a considerable amount of arsenic has been destributed over a wide area around the site.

Roasting in the more recent generation of plants is carried out in fluid bed roasters which provide a much cleaner control of gases than was the case with the older Edwards roasters although undoubtably these could also be designed to avoid gas leakages. There are roasters operating today in some of the more remote parts of the world where there is virtually no attempt made to recover arsenic from the gas steam. In the U.S.A. today, there are no operating gold plants which operate roasters. In Canada, the remaining roasting plants have installed highly efficient gas cleaning systems for arsenic recovery. In Ghana, the prevailing wind direction is obvious as judged by the denudation of the jungle downwind from the plant.

The treatment of roaster gases from arsenopyrite roasters has been improved to such an extent that technology exists to remove arsenic to such low levels from the gas stream that arsenic emissions should no longer prevent the use of roasting as a metallurgical tool. More likely, it is the economics of SO_2 removal and the associated cost of disposing of the sulfuric acid generated. A very thorough statement of the state of the art in arsenic removal from roaster gases was prepared by MARCHANT and MEEK (1980) of the Industrial Environmental Research Laboratory, Office of Research and Development, U.S. EPA, Cincinnati, Ohio, 45268.

One of the major breakthroughs in arsenic recovery from roaster gases is the successful use of Dralon baghouses to collect As_2O_3 after the gases have passed through a hot electrostatic precipitator for dust removal and then been cooled to condense the arsenic. The innovative "quench bend" for rapid cooling of the gases developed by HATCH ASSOCIATES and installed by DORR OLIVER in Australia seems to be important in avoiding problems in the baghouse due to arsenic condensation. Arsenic condenses at a temperature not that much higher than the condensation of water vapor in the gas stream which, of course, would generate sulfurous acid on the bag surfaces and make a mess of the baghouse. Consultants who are familiar with details of this aspect are:

D. W. ROSTRON

Baghouses for collection of arsenic troxide particles at around 150°C from the cleaned roaster gas are provided by:

FLAKT AUSTRALIA LTD.
124 Pacific Highway
St. Leonards N.S.W. 2101
(02) 439-8000
John Porter

Information on roasting and arsenic collection was provided in a chapter of the RANDOL Report "Innovations in Gold and Silver Recovery - Phase II" and by ROSTRON (1982), WRIGHT (1961), FOSTER (1963), MORTIMER and TAIT (1959), and GOODFELLOW et al. (?). The quench bend was described in the latter publication, and more information would likely be available from:

HATCH ASSOCIATES LTD.
21 St. Clair Avenue East
Toronto, Ontario
(416) 962-6350

ROBINS (1984) refers to a company in England that has developed a process to convert arsenic in hot roaster gases as arsenic sulfide which is much easier to separate from gas streams. This work has apparently been supported by BRITISH PETROLEUM, and a pilot plant is available for testing and demonstration. The company is:

REDLAC METALLURGICAL PROCESSES LTD.
148 Buckingham Palace Road
London SW1
England
(01) 730-7266

Apart from removal of arsenic from flue dusts, there is also a possibility that if sulfuric acid is generated to remove SO_2 from the gases, this will be contaminated by arsenic

which could limit the marketability of the acid. OHSAKO and YONEYAMA (1973) described one case where sulfuric acid contained 200-500 mg As/l.

ARSENIC FLUE DUST DISPOSAL

Arsenic control in roaster gas and in solid dusts generated is an important part of overall water quality management. Arsenic removal from the roaster gas is only one side of the problem, however. Once recovered, the dusts must be stored and disposed of safely. There is a wide range in methods employed for arsenic sludge and arsenic dust disposal.

The safest and most permanent disposal for arsenic dust is to sell it to an arsenic product manufacturer. This is, in fact, what some generators of arsenic do. For example, the government roasting plant at Kwekwe in Zimbabwe upgrades their arsenic dust and sells it to a user in South Africa. GIANT YELLOWKNIFE MINES LTD. sells some of the arsenic that is produced from their gas stream, and the operation at Salsigne, France, employs a novel shaft furnace to roast arsenopyrite concentrate which yields an arsenic flue dust of exceptional purity. The problem is that at both GIANT and the Zimbabwe roasters, very much more dusts are generated that there are markets for.

GIANT YELLOWKNIFE has developed one of the most innovative arsenic dust storage approaches. Arsenic dust is pneumatically pumped into specially prepared chambers in the underground workings which are in permafrost.

A giant truck-mounted vacuum cleaner is kept on hand to clean up any accidental arsenic spills and to reinject the collected dust into the underground storage. Provision is also made to store the dust in above-ground silos for shipping when there is a market.

At the Con Mine of COMINCO, which has long since ceased roasting arsenopyrite concentrates, a chemical plant has been installed to recover a very pure arsenic oxide product from dust generated over a decade ago and stored underwater in ponds. This approach has required a capital expenditure of $12 million and was partially motivated by the cost of alternative methods of disposing of the arsenic safely.

At the Fairview Mine, Barberton, South Africa, the only dusts collected are those that settle in a flume between the roaster and the stack. This dust is stored in an impoundment constructed from roaster coal ash. Seepage drains to groundwater and a nearby stream.

At ASHANTI GOLD MINES LTD. in Ghana, all arsenic is discharged with the roaster gas to the atmosphere leaving an unsightly scar in the remote jungle location.

Canadian and Australian operations are the most advanced in arsenic removal from roaster gases which has a positive impact on reducing arsenic levels in surface and groundwater in their surroundings. GIANT YELLOWKNIFE MINES LTD. is described in a trip report in Appendix I. There are no arsenopyrite roasters in the U.S.A., and there would be no state in which such a plant could be installed without the most exacting scrutiny.

BELL (1973) described how the abandoned Deloro Smelting and Refining site in Ontario led to arsenic contamination of the Moira River years after operations ceased due to groundwater migration from calcium arsenite ponds which had been covered over. This led to the owners being forced to stabilize the site more than a decade after the site had been abandoned. How arsenic dusts and sludges are disposed of is considered to be a critical aspect of arsenic control with respect to water quality and effluents from the plantsite both during and after the life of the operation.

EQUITY SILVER MINES, Houston, British Columbia, is believed to have shipped a calcium arsenate precipitate (after dewatering in a filter press) to a hazardous waste disposal site in Oregon which sounds like an expensive excercise.

TREATMENT TECHNOLOGY FOR ARSENIC

PATTERSON (1975) and ROBINS and TOZAWA (1982) pointed out that limited information was available on the levels of arsenic in industrial wastes and on current wastewater treatment processes. Although this investigation was able to find some information on arsenic removal from several more recent mine-mill effluent treatment installations, the information gathered by PATTERSON (1975) for arsenic removal from drinking water may be useful since the methods for arsenic treatment of drinking water and metallurgical and mine effluents are similar.

ROBINS (1983, 1984, 1985); ROBINS and TOZAWA (1982), NISHIMURA, et al. (1983), and NISHIMURA and TOZAWA (1977) have made significant contributions to the better understanding of the solubilities and precipitation mechanisms of arsenic although they have done more to point out the long-term instabilities of arsenic precipitate sludges due to the action on them by dissolved CO_2 than they have to find a practical and usable solution to the problems of removing arsenic from mine-mill tailings effluent solutions and disposal of the precipitates. These authors showed that calcium arsenate and ferric arsenates are insoluble and form precipitates which are not stable. The implications of this are that arsenic, once precipitated and settled in a decant pond, may not remain stable for long as CO_2 from the atmosphere dissolving in the water covering the precipitate sludge will gradually convert some precipitates to calcium and ferric carbonate rendering the arsenic from the precipitate soluble. Most of their tests are performed on relatively pure laboratory solutions, and there are practical effluent disposal sites where their laboratory derived conclusions could readily be tested.

A lead smelter in eastern Canada (see Lead Smelter B in Appendix I) treats lead-bearing flue dusts containing arsenic. The recycling dusts introduce arsenic, cadmium, zinc, etc. to a scrubber system, and arsenic gets into the plant effluent stream. Conventional lime settling removes the base metals, and original plans called for precipitation of arsenic with iron. However, this has not worked quite as well as

planned, possibly because the iron is added after the lime or because the arsenic is in the trivalent arsenite (AsO_2^-) form as opposed to the pentavalent arsenite (AsO_4^{-3}) form which precipitates with iron. Pilot tests are underway to determine how chlorine or peroxide oxidation of the solution will improve the arsenic removal process.

GIANT YELLOWKNIFE MINES LTD. oxidizes cyanide using alkaline chlorination which also oxidizes arsenic in the effluent which is then precipitated with ferric sulfate. This is accomplished in two energetically agitated tanks followed by flocculant addition in a third reactor prior to discharge to a large decant basin where the precipitated arsenate settles as a reddish brown sludge.

EAST RAND GOLD AND URANIUM MINES LTD. (ERGO) generates arsenic in solutions used to quench and wash calcines after pyrite roasting. The pyrite is recovered by flotation from old tailings dams. The calcine wash solution is treated by adding iron-rich acidic solvent extraction raffinates followed by intense air agitation while adding lime--this reduces arsenic from 9.3 ppm to below 0.5 ppm. Undoubtably, the presence of small amounts of iron base metals in the calcine wash solution help to co-precipitate the arsenic.

The Con Mine gold cyanidation tailings are treated with sodium sulfide and ferrous sulfate at the tailings outlet to a large, shallow, segmented pond and when necessary, augmented by broadcasting over the decanted effluent pond surface prior to discharge.

Low Solubility Arsenates of Pb, Cu, Cd, Ni, and Zn at pH 4-8	-	-	-	Robins and Tozawa (1982)
Algae as Uptake - Biological	-	-	-	Spisak (1978)

*Note: ROBINS (1985) shows that the solubilities of barium arsenates are much higher than believed, and that the basis for the patent is not well founded.

**Note: ROBINS (1984) found that above pH 4, arsenic converts from As_2S_3 to a soluble form.

***Note: ROBINS (1984, 1985) finds that these Ca arsenates and Ba arsenates are unstable in the presence of dissolved carbon dioxide.

$FeSO_4/Na_2S$ effectively reduces cyanide levels in the tailings which are discharged at a high pH (10-11) after gold cyanidation. The $FeSO_4$ also precipitates arsenic to a sub-ppm level. There are several interesting aspects of this approach to arsenic removal.

Ferrous sulfate rather than ferric sulfate addition offers four advantages according to KUIT (1985):

1. Because there is no vigorous agitation, iron added in ferric form would rapidly convert to ferric hydroxide which would not carry too much arsenic with it under these conditions.

   Ferrous sulfate slowly oxidizes to ferric and provides a better opportunity for the gradually generated ferric hydroxides to absorb arsenic because conditions are more favorable for co-precipitation than if the iron was all immediately precipitated as ferric hydroxide. This, at least, is a logical explanation of the phenomenon that was found to occur during empirical tests.

2. Ferrous sulfide in the presence of sulfide forms FeS which provides a reserve of sulfide ions which pull base metals such as Cu, Ni, etc. from complexes, including cyanide complexes. Ferrous and ferric ions remove cyanide effectively as a precipitate. The base metals co-precipitate with arsenite and/or arsenate as found by ROBINS and TOZAWA (1982).

3. Ferrous sulfate is easier to handle than the extremely corrosive ferric sulfate.

4. Ferrous sulfate is considerably less expensive than ferric sulfate.

ROSEHART and LEE (1972) refer to a gold ore extraction process waste stream at pH 9.5 containing 900 ppm particulate arsenic and only 10.1 mg/l soluble arsenic. The soluble arsenic, constituting only 1% of the total arsenic present, was in the arsenite form. A second stream described at pH 3.1 contained 880 ppm particulate arsenic and 132 mg/l

(13%) soluble arsenic. LARSEN, et al. (1973) described acid mine drainage in the Rocky Mountains containing 6.0-22.0 mg/l soluble arsenic. Arsenic wastes from nonferrous smelting have been reported where the main form appears to be extremely small (1-3 u diameter) particles from which arsenic could profitably be recovered. SWAIN (1939), DEAN, et al. (1972), and STOOF and HAASE (1938). However, most people in the mineral processing industry would be able to find relatively abundant sources of cheap arsenic today without having to filter such fine particles.

ARSENIC IN GOLD AND SILVER MINE AND MILL EFFLUENTS

Arsenic finds its way into minewater when oxidation of underground sulfides occurs which can, if arsenic is contained in the ore, introduce some arsenic into the acid mine drainage. Seepage from tailings ponds can also introduce arsenic into minewater. Later in this discussion, mention is made of an interesting and simple method of treating acid mine drainage containing arsenic.

Arsenic finds its way into tailings decant water and mill effluents in different ways, too, depending on how the arsenic is present and the type of process employed:

- Where concentrates are roasted ahead of cyanidation, some arsenic, if present in the concentrate, will get into solution during water quenching of the calcine prior to leaching.

- Unless arsenic is efficiently removed from the roaster gas stream, it can be distributed to the area surrounding the plant site where it will contaminate surface drainage from precipitation.

- If arsenic dusts and sludges are not disposed of in a stable fashion, these can introduce arsenic into both runoff and seepage water.

- At El Indio, gold copper sulfide concentrates are roasted to reduce arsenic. How the concentrates and roaster gas condensed dusts are handled can affect arsenic levels in effluents from this type of plant.

  Much of the groundwater available near the El Indio mine site was contaminated by nature with metals including arsenic and has been that way since before mining started.

- The new HOMESTAKE McLaughlin project will treat ore by pressure oxidation to make gold amenable to cyanidation. The oxidized ore will be washed before cyanide leaching to remove base metals and arsenic; the arsenic and metals will then be precipitated from the washwater in a separate circuit and discharged in the

precipitate sludge (thickener u/f) to the impermeable (subaerial) tailing impoundment.

Rex Guinivere
Vice President, Engineering

- The new Hemlo gold project of NORANDA MINES LTD. and TECK CORP. uses neither roasting nor pressure oxidation, and arsenic is still expected to range between 0.5-2.0 mg/l in the wastewater. It will be reduced to below 0.5 ppm by treatment which will employ SO_2-air for cyanide destruction and $Fe_2(SO_4)_3$/lime addition in agitated tanks for removal of more persistent metals. Both steps would reduce arsenic levels.

  Information on water treatment facilities and processes to be installed at Hemlo can be requested from:

Arsenic is present in high concentrations in ores that more often than not are classed as "refractory." The ultimate fate and distribution of arsenic in tailings and effluents from the operation depends to a large extent on the process employed to treat the ore. Most recently, the trend in treatment of sulfide ores has been away from roasting and toward hydrometallurgical approaches such as pressure oxidation. WEIR and BEREZOWSKI (1984) describe the Sherritt-Gordon pressure oxidation process for the treatment of sulfide ores. As in the case of HOMESTAKE's McLaughlin project described by KUNTER, et al. (1984) and GUINIVERE (1984), arsenic can be removed to low levels in the presence of iron solubilized during oxidation of the pyrite as well as other metals.

There are five aspects to controlling arsenic in effluents:

- Trace amounts of arsenic may require treatment of the total effluent to meet discharge limits, perhaps in conjunction with cyanide and other metals removal.

- Segregation of smaller, more concentrated flows may make it possible to solve the problem with lower overall capital and operating costs.

- Prevention is better than cure. As noted above, as much arsenic as possible should be prevented from reaching the environment where a more expensive cure may be necessary.

- In roasting plants and calcine cyanidation, it is likely that all effluent streams will contain some arsenic, although the most concentrated stream is likely to be the calcine washwater.

- In treating arsenic-bearing effluents, precipitate sludges are commonly produced. It is necessary to consider the long-term stability of these sludges in the manner in which they are disposed of.

The following summarizes some of the measures adopted to remove arsenic from gold and silver mill effluents. More detailed accounts are included in trip reports for GIANT YELLOWKNIFE, THE CON MINE, and ERGO in Appendix I.

ARSENIC IN SILVER RECOVERY OPERATIONS

Arsenic frequently occurs with silver in sulfosalts which are also likely to contain antimony, copper, iron, and of course sulfur, e.g. tetrahedrite $(Au\ Ag\ Fe)_{12}\ Sb_4\ S_{12}$ and Tennantite $(Au\ Ag\ Fe)_{12}\ As_4\ S_{13}$. In fact, arsenic occurs in many silver minerals and sulfide minerals that are recovered with sulfide concentrates containing silver, e.g.:

Enargite $Cu_3\ As\ S_4$, Billingsleyete $Ag_7\ (As\ S6)S_6$, Esmitite $Ag\ As\ S_2$, Hutchinsonite (PbTl) (Cu Ag) As_5S_{10}, Kutinaite $Au_2\ Ag\ As$, Laffithte $Ag\ Hg\ As\ S_3$, Langenbachite $Pb_{37}\ Ag_7\ Au_6\ As23\ S_{78}$; Marrite P6 $Ag\ As\ S_3$; Novakite $(Au\ Ag)\ As_3$, Perceite (Ag-Cu)16 $As_2\ S_{11}$; Smithite $Ag\ As\ S_2$; Trechmanite $Ag\ As\ S_2$ and Xanthoconite $Ag_3\ As\ S_3$, etc.

Arsenic contained in concentrates shipped to smelters is disposed of at that end of the operation, but inevitably some arsenic remains in the tailings and wasterock.

EQUITY SILVER MINES LTD. is an interesting, although unique, example of ways to deal with arsenic and other contamination.

Silver, gold, and copper occur with sulfide minerals in EQUITY SILVER ores which occurred in two ore zones, the higher grade Southern Tail Zone and the Main Ore Zone. Each of those has led to different arsenic disposal methods. In addition, EQUITY SILVER has developed a simple, yet effective, acid mine drainage treatment which meets the British Columbia Special Wastes Act exemption criteria.

A flotation concentrate with 17% Cu, 7,000 g Ag/t, and 15 g Au/t but with 7% Sb and 4% As was produced from the Southern Tail Zone. In order to meet concentrate sales specs of max. 0.6% Sb and 1.6% As, the concentrate was pressure leached using the EQUITY SILVER process. In the end, this cost C$10 million in research and development and C$46 million in capital to build a plant to treat 2,500 tpm concentrate. This ore type was exhausted in 1984, and the plant was shut down. Nevertheless, the approach to arsenic and antimony removal from the silver-copper concentrate is of interest. It is also an example of how, even with some of the industry's top metallurgical brains to help, developing and installing complex new processes can be more trouble and expense than originally expected.

In a two-stage counter current batch caustic leach with fresh NaHS, the antimony and arsenic is removed from the concentrate and separated in solution from the concentrate by pressure filtration.

Leached concentrate was then repulped and rinsed with water prior to pressure filter dewatering and shipment. This step is necessary because the lower pH reduces the pyrophoric nature of the concentrate.

Leach liquor advances from the primary circuit to the secondary leach circuit. Liquor filtered off after the secondary leaching contains As and Sb and is treated sequentially for antimony recovery, arsenic recovery, and sodium sulfate crystallization. Excess sodium sulfate is generated as a reaction product during arsenic and antimony crystallization and must be bled before the leach liquor is recycled.

In contrast to SUNSHINE MINING which uses sulfur and NaOH to make a Na_2S, NaHS, and $Na_2S_2O_3$ lixiviant to remove As and Sb from a copper silver concentrate, EQUITY SILVER used NaHS generated by mixing Na_2S and NaOH. $Na_2S_2O_3$ was avoided because it would have dissolved gold which would be precipitated again with the sodium arsenate in the solution treatment step.

The EQUITY SILVER process is described in the following flowsheet from E/MJ January 1982.

Source: E&MJ January, 1982

SOLUTION TREAMENT

Filter-press filtrate is passed through a polishing filter to remove residual fines before being pumped to the Sb removal section. It contains Sb, As, NaOH, and Na_2S.

The liquor was held at 85°C and then autoclaved in 5/8" carbon steel autoclaves lined 3/16" nickel 200 cladding. Monel piping was used. Three autoclaves were installed in parallel with a fourth as a spare. Once filled, the autoclaves were held at 150°C and 80 psi O_2 for about 1-2 hours; then the contents of the autoclaves were discharged into an 8'Ø x 16' flash tank where premire is lowered. Much water evaporates, and sodium antimonate crystallizes out. The liquor contained around 8% solid Na antimonate with 50-100 g/l NaOH solution which is fed to a belt filter. After washing twice, it is packed for shipment. Liquor advances via a holding tank to the arsenic removal circuit.

Calcium arsenate was precipitated by adding lime to a 10' x 10' tank ahead of autoclaving the liquor. The formation of calcium arsenate requires a very high oxygen pressure and temperature to complete the oxidation of thiosulfate to sulfate.

Arsenic precipitation is accomplished at 190°C and 230 psig O_2, and after 1-2 hours conversion of arsenic to sparingly soluble Ca arsenate, all thromlfate has oxidized to sulfate. Release of the autoclave contents to a flash tank loses 12% volume through water evaporation. Crystals of calcium arsenate are separated from the liquor in a Bird centrifuge. Crystals from the centrifuge discharge contained about 50% moisture and are repulped and pressure filtered. The liquor fraction from the 38 chamber Lasta pressure filter joins the centrate fraction from the centrifuge for treatment in the sodium sulfate removal circuit.

SODIUM SULFATE RECOVERY

Liquor, after arsenic removal, contains small amounts of entrained solids and excess sodium sulfate generated during autoclaving of antimony and arsenic. This liquor has a trace amount of arsenic, and so the sodium sulfate circuit was equipped to remove it.

A polishing filter is used to remove traces of suspended solids from the liquor fed to the sodium sulfide section. Liquor is then stored in holding tanks serving a triple effect evaporator supplied by HPD Corp., Pittsburgh, Pennsylvania. The triple effect evaporator uses steam counter currently. NaOH is added to the holding tanks to salt out the Na_2SO_4 ahead of the triple effect evaporator which concentrates the Na_2SO_4 to the point of crystallization. Na_2SO_4 is separated out on a belt filter allowing the caustic solution to be recycled to the primary concentrate thickener.

The filtered Na_2SO_4 crystals contain entrained arsenic. To strip out the arsenic, the Na_2SO_4 crystals must be redissolved in a pair of steam heated reaction tanks to which lime or sulfuric acid are added to adjust pH. Arsenic is precipitated as calcium arsenate and subsequently removed from the liquor by centrifuge. The liquor 's polished and evaporated in a double-effect crystallizer with chambers at 96°C and 123°C respectively. Na_2SO_4 crystals were dewatered in a hydrocyclone followed by two centrifuges before passing through a 3' x 16' long rotary drier.

The double and triple effect crystallizers for Na_2SO_4 recovery were supplied by:

A. H. LUNDBERG EQUIPMENT LTD.
150-10551 Shellbridge Way
Richmond, B.C. V6X 2W8
(604) 273-5204

Anticipated by-products and waste from treating around 2,500 tpd concentrates was 500 tpm sodium antimonate, 600 tpm calcium arsenate, and 1,200 tpm Na sulfate.

The batch process required many sensors and microprocessors. EQUITY SILVER has installed a microprocessor system supplied by:

PROCESSING THE MAIN ZONE

The Main Zone can be treated by flotation to recover an acceptable grade of concentrate with As and Sb levels acceptable for shipment.

PROCESSING SOUTHERN ZONE TAILINGS

Flotation of Southern Zone tailings under different conditions allows a pyrite-arsenopyrite concentrate containing gold to be recovered. EQUITY SILVER has reputedly accumulated some 60,000 t of arsenopyrite-pyrite concentrates containing some gold.

Conventional cyanidation recovers only 15% of the gold content from this refractory concentrate. However, by oxidizing 6-10% of the sulfide content, recovery is increased to the 90% range. This 6-10% sulfide corresponds to the arsenopyrite content of the ore, although some pyrite is also oxidized.

EQUITY SILVER is currently building a vat bio-oxidation process to selectively oxidize arsenopyrite without attacking the pyrite to liberate the gold and silver values. This process is to be described by MARCHANT (1985).

In the bioleaching process, arsenic is solubilized with numerous other cations at an operating pH of 0.9. There is a ferric ion concentration of 5-8,000 ppm which oxidizes all arsenic to arsenic (+5) as long as the Fe^{3+}/As ratio is kept above four. The bioleach liquor is recycled in the process to conserve nutrient additions, but a bleed stream is taken off to remove arsenic and other excess impurities. This bleed stream is partially neutralized to pH 3 with soda ash to precipitate arsenic as ferric arsenate. (Once arsenic is completely in the arsenate form, it could be precipitated several ways

including as copper arsenate if desired to make an intermediate product.) Once all the arsenic has precipitated lime is added to pH 9 to precipitate the remaining metals, Fe, Cu, Zn, etc.

The sludge is disposed of as acid mine drainage sludge (as described below) to the tailings pond. EQUITY SILVER has shown that this sludge meets the B.C. disposal criteria when mixed with tailings (the same as the EP acetic acid test) and is currently conducting long-term pond stability tests.

EQUITY SILVER MINES' address was shown above. It is believed that B.C. RESEARCH assisted in developing the bench scale process:

TREATMENT OF ACID MINE DRAINAGE

EQUITY SILVER MINES LTD. has developed and installed a simple, yet effective, acid mine drainage control system that meets British Columbia's very strict environment protection regulations. The AMD sludge, when mixed with tailings solids in a ratio of one sludge to four parts by volume mill tailings slurry at 35% solids, yields a settled tailings residue that meets the criteria for exemption from the B.C. Special Wastes Act. These criteria involve a leachability test similar to the U.S. EPA EP leach test using acetic acid.

Lime is added from an automatic lime slaker directly to a reaction tank. The reacted effluent is allowed to settle out precipitate in a sludge settling pond.

According to EQUITY SILVER staff, when this sludge, which includes precipitated arsenic, is mixed with the tailings slurry, the precipitate remains stable and meets the EP leach test. Although possibly not a suitable criteria for long-term stability testing from a chemistry point of view, the buffering nature of dissolved solids and excess alkalinity in the tailings is said to avoid CO_2 effects found in pure solutions/precipitate by ROBINS and TOZAWA (1982) and ROBINS (1984).

The sludge generated from the bio-leach pilot plant effluent treatment process is found to behave in the same way yielding a stable waste when mixed with tailings. EQUITY SILVER is currently running simulated long-term pond stability tests which take into account thiosulfate effects which seasonally reduce the pH of the tailings decant during the spring runoff.

Based on success at Key Lake in encapsulating arsenic precipitates in sub-aerial tailings which have extremely low permeabilities, EQUITY SILVER is also testing this technique with its tailings. In retrospect, this approach could also potentially have saved costs when disposing of its pressure oxidaton calcium arsenate sludges.

ARSENIC FROM ACID MINE DRAINAGE

In addition to the results on AMD treatment reported by EQUITY SILVER MINES LTD., the EPA INDUSTRIAL ENVIRONMENTAL RESEARCH LABS in Cincinnati, Ohio, found that lime neutralization, reverse osmosis, and ion exchange removed As, Cu, Hg, Ni, Se, and Zn from acid mine drainage but did not remove B or P. Although reverse osmosis and ion exchange were slightly more effective overall than neutralization, the

chemical requirements and need for subsequent waste treatment offset their advantages.

ARSENIC FROM COPPER AND LEAD SMELTERS

Arsenic removal is necessary from most copper and lead refineries. Arsenic accumulates in roaster flue dusts which are recycled in many cases resulting in further concentration. Gas scrubbing in roaster and smelter gas entrainment systems results in arsenic entering the water system. Also, concentrate and flue dust stockpiles, as well as loading and handling areas, may become contaminated. Areas around older roasters and smelters prior to recent air cleaning requirements may have been contaminated by fallout from stackgasses, possibly over many years' prior operations.

According to PATTERSON (1975), arsenic wastes from nonferrous smelting has been reported in the form of extremely small (1-3 u diameter) particles from which arsenic could profitably be recovered as described by SWAIN (1939).

Where sulfuric acid is produced from such operations, it is possible that some residual arsenic will end up in the acid according to OHSAKO and YONEYAMA (1973). They report cases where acid contained 200-500 mg arsenic. They also describe how this acid was treated.

A literature search yielded the following references to arsenic removal from copper and lead smelters:

DIMITROVA, M.G. (1971-1972) - Selection of cobalt ions in aqueous sulfuric acid medium were recovered selectively by flotation of sediments. Following this, Zn, As, and Pb ions from the clarified water are separated by precipitation as hydroxides by limewater.

REBROVA, et al. (1977) found that the arsenic levels in wastewaters from a Pb-Zn plant varies between 0.1-0.4 g As/l at pH 12-12.5. Tests using: 1) $FeSO_4$; 2) Fe SO_4 and $H2SO_4$; and 3) a two-stage method of applying $FeSO_4$ with subsequent neutralization with a mixture of lime and soda ash at a ratio 2:1 were tried. $FeSO_4$ alone yielded satisfactory results (98-99%) when Fe:As ratios of 7:1 and 9:1 were used at pH 7-7.5. The use of H_2SO_4 to adjust pH to 10-10.5 and $FeSO_4$ addition worked well at a ratio of Fe:As of 5:1, but the two-stage method worked most efficiently.

SCHWITZGEBEL, et al. (1979) studied the path of arsenic through a copper reverberating furnace and is an interesting example of how a material balance for arsenic is computed for a unit operation. Their paper is inserted below, and more information or help in this sort of survey may be requested from:

RADIAN CORPORATION
8500 Shoal Creek Blvd.
Austin, TX 78758
(512) 454-4797
Klaus Schwitzgebel

At Lead Smelter B in eastern Canada, lime settling and flocculated clarification has not achieved perfect arsenic removal in effluents for discharge. BRUNSWICK SMELTING staff were testing the effect of oxidation of the arsenic using Cl_2 and peroxide to improve the process. In the absence of adequate excess ferric ions, the arsenic was not precipitating well.

At this lead smelter, the 170 m^3/d effluent treatment plant has failed to remove arsenic. As a result of the recycling of in-plant generated flue dusts and sludges from the effluent treatment plant as well as the addition of flue dust containing arsenic from other plants to feedstocks and the recirculation of slag granulation water which is integrated with the plant effluent system, average arsenic levels in the effluent system are building up steadily. Arsenic levels vary significantly from day to day, and there is speculation that accumulation of arsenic precipitate in the holding and cooling pond sediment may be responsible for sporadic releases of arsenic back to the effluent.

SHIMOIIZAKA and MATSUOKA (1975) reviewed (in Japanese) the precipitation of metal hydroxides by neutralization with $CaCO_3$ and $Ca(OH)_2$. The effects of coexisting ferrous/ferric ions on the precipitation of Cd^{24}, AsO_4^{3-2}, and the oxidation of ferrous ions with air, bacteria, and oxidants in the presence of a catalyst were reviewed.

BOLIDEN, SKELLEFTHAM, SWEDEN

BOLIDEN at its Skeileftham copper smelter and metallurgical plant in Sweden employs sulfide precipitation of metals from metallurgical effluents at several points in their plant.

The U.S. EPA sent a team of investigators to describe the operation and performance of the operation which was documented in a report with Order Number PB81-209272 and EPA Summary Report EPA-600/S2-81-081, August 1981, by BLYTHE, et al. (1981).

The influent solution contains arsenic, other metals, and about 120 ppm F^- as well as 650 ppm SO_3. The use of sulfide precipitation at high pH would fail to remove arsenic effectively and would precipitate CaF_2 which is contaminated with metals and therefore unfit for land disposal. Low pH sulfide precipitation does not precipitate fluoride. Also, the use of sulfide at a low pH in the presence of sulfite results in excess sulfide consumption with generation of sulfur and thiosulfate.

To best meet all these conditions, metal sulfides are precipitated at pH 3.9 which has to be maintained by NaOH addition until all metals are precipitated. Sulfide addition is

controlled using a pH meter which shows a distinct increase when all metals are precipitated during controlled rate addition and multi-media filtration followed by lime addition and settling to remove fluoride, as illustrated schematically by BLYTHE, et al. (1981) below. Arsenic is reduced from 156 mg/l in the influent to 33 mg/l in the low pH sulfide precipitation and finally to 4 mg/l after lime precipitation and settling. It is surprising that arsenic is not removed much lower than this. Removal of other metals, however, appears to be very effective as seen on the diagram. In the case of BOLIDEN, the metal sulfide precipitate is stored in tanks pending development of a hydrometallurgical process to recover the metal values.

Typical residual metal concentrations obtained by full-scale test run (Boliden Metall).

D. BHATTACHARYYA
Chemical Engineering Dept.
University of Kentucky
Lexington, KY 40506-0046
(606) 257-2798

According to BHATTACHARYYA (1985, personal communication), one of the problems is excessive cost at low pH due to $SO_3^=$ consumption of sulfide and the efficient removal of metal sulfides by settling and filtration. Especially copper forms very finely divided sulfide precipitate which is difficult to remove. Another problem is the less effective precipitation of weaker sulfide precipitates in the presence of chelating agents such as cyanide.

ARSENIC DISCHARGE FROM A PRIMARY COPPER SMELTER

Klaus Schwitzgebel*, R. V. Collins*, R. T. Coleman*

Proc. International Conference on
Management & Control of Heavy Metals
in the Environment. London Sept. 1979

ABSTRACT

In this study, the path of arsenic through a copper reverberatory furnace was determined. 50% of the arsenic entering the furnace in the concentrate feed exited in the off-gases, 25% left with the slag, and 25% was transported to the converters in the matte.

In addition, arsenic concentrations at the inlet and outlet of the electrostatic precipitator (ESP), the blowdown of the sulfuric acid plant, and concentrate feed are reported. One major arsenic compound in the discharge from the reverberatory furnace ESP was determined by X-ray diffraction to be arsenic trioxide, As_2O_3. Arsenic emission rates from the ESP as a function of time varied between 25 and 140 pounds per hour. These fluctuations were due partly to variations in the concentrate arsenic composition and partly to intermittent recycling to ESP dusts.

INTRODUCTION

The original goal of this study was the evaluation of the electrostatic precipitator performance servicing the reverberatory furnace (ref 1). Cross-checking of the arsenic emission rates by plant personnel broadened the scope considerably.

The smelter studied has a daily production capacity of 200 tons anode copper. The gas flow from the reverberatory furnace to the ESP is 160,000 acfm. The precipitator operated at approximately 600°F which is above the dew point of sulfuric acid. Certain arsenic compounds are volatile at 600°F and escape the ESP uncontrolled.

The article describes the smelting operation, the sampling, the analytical techniques, the arsenic flow rates and arsenic emissions.

SMELTER DESCRIPTION

The major pieces of equipment for the copper smelter studied are: 1) reverberatory furnace; 2) converters; 3) anode furnace; 4) casting wheel; and 5) gas and particulate control equipment.

The reverberatory furnace is green fed. The off-gases are cooled in two waste heat boilers (WHB), cleaned in two electrostatic precipitators (ESP) in parallel, and discharged to the stack. Deposits formed on the WHB tubes were periodically removed using steam sootblowers. Dust collected in both the waste heat boilers and electrostatic precipitators is recycled to the feed preparation area.

The off-gases from the converters are treated in a similar fashion. Heat is recovered in waste heat boilers. Particulate matter settles in the balloon flue and is retained in the electrostatic precipitator (ESP). Dust collected in the WHB is recycled directly to the converters. Balloon flue and ESP dusts are recycled to the reverberatory furnace feed preparation area. The SO_2-rich converter gases are then cleaned in a gas conditioning unit followed by a wet electrostatic precipitator. Sulfur dioxide is finally oxidized catalytically to produce 93% sulfuric acid in a single contact acid plant.

The concentrate is the only significant arsenic-containing feed stream. Arsenic-containing discharge streams are the reverberatory furnace slag, acid plant blowdown, anode copper, and the gases discharged from the electrostatic precipitator to the stack. The arsenic

entering with the fuel and flux material and exiting with the sulfuric acid plant tail gas can be neglected.

SAMPLING

Four approaches were chosen to quantify the arsenic discharge from the reverberatory furnace ESP: 1) a material balance approach around the plant for arsenic; 2) a filter impinger train used at the reverb ESP exit; 3) a wet electrostatic precipitator followed by an impinger train at the ESP exit; and 4) a modified EPA Method 5 train at the ESP exit.

The material balance approach used to arrive at discharge averages for two entire months was based on the As flows (lb/hr) according to the following equation:

ESP Discharge	=	Concentrate Feed	+	Flux & Fuel	-	Reverberatory Furnace Slag	-	Anode Copper

The filter impinger train was used by plant personnel to cross check the results.

The wet electrostatic precipitator (WEP) which preceded an impinger train was 3" in diameter and 2' tall. Ultrapure dilute nitric acid was circulated through a 500 ml round bottom flask and a vertical glass cylinder by a peristaltic pump. The walls of the cylinder were wetted by the falling film of electrolyte. A thin platinum wire was suspended in the center of the glass cylinder. A corona discharge at the center electrode was generated by a 12 to 15 kV DC voltage. The gas flow rate through the WEP was approximately 0.5 ft^3/min. The gas entering the WEP was first scrubbed and cooled in the round bottom flask. Particulates and mist not retained here were electrostatically charged in the glass cylinder, collected in the falling film, and washed into the electrolyte reservoir. This sampling device does not clog like a filter or thimble and no analytical background corrections are necessary as are needed with filters. Contents of the eight impingers following the WEP were 1:1:1 H_2SO_4-HNO_3-H_2O(#1,2), dry impingers (#3,7), 20% KOH (#4,5), H_2O_2 (#6), silica gel (#8).

ANALYSIS

Liquid samples were filtered and the solids digested using nitric and perchloric acids. Insoluble silicates were subjected to an HNO_3/HF digestion. The filtrate and digested solids were combined for analysis.

Samples for arsenic analysis were complexed as the heteropoly acid of molybdenum. Quantitative determinations were made by injecting an aqueous aliquot into the graphite furnace attachment of an atomic absoption spectrophotometer. This method of analysis was developed by Ramakrishna, Robinson, and West (ref 2), and Ediger (ref 3). The complexing step avoids the volatilization of arsenic compounds at low temperatures, thus a charring temperature of 1200°C could be used. Working at this temperature also reduces interferences experienced at lower temperatures.

ARSENIC DISCHARGE DETERMINED BY MATERIAL BALANCE DIFFERENCE

The weight fractions of arsenic in the incoming or outgoing streams (lb As/lb) multiplied by the stream flow rates (lb/hr) give the arsenic flow rate in the corresponding streams in lb As/hr. This material balance approach was used to estimate the amount of arsenic escaping the reverberatory furnace electrostatic precipitator. The following average rates were found during the month of January 1977.

Incoming Streams:			Outgoing Streams:		
Concentrate Feed	102	lb/hr	Reverb Furnace Slag	26	lb/hr
Flux and Fuel	0	lb/hr	Acid Plant Blowdown	27	lb/hr
TOTAL ARSENIC IN	102	lb/hr	Anode Copper	5	lb/hr
			Reverb ESP Discharge	X	lb/hr
			TOTAL ARSENIC OUT	58 + X	lb/hr

Reverb ESP Discharge = 102 - 58 = 44 lb/hr

These data indicate that roughly 50% (44.6 lb/hr) of the incoming arsenic (102 lb/hr) leaves the smelter with the reverberatory furnace flue gas, 25% (26 lb/hr) is discharged with the reverberatory furnace slag, and 25% (27 lb/hr) is transported with the matte to the converters. The same 50-25-25 split was indicated in the reverberatory balance for arsenic based on the samples obtained during the July 1976 sampling effort.

The same balance approach repeated during March 1977 showed the following results:

Incoming Streams:			Outgoing Streams:		
Concentrate Feed	103	lb/hr	Reverb Furnace Slag	31	lb/hr
Flux and Fuel	0	lb/hr	Acid Plant Purge Water	27	lb/hr
TOTAL ARSENIC IN	103	lb/hr	Anode Copper	5	lb/hr
			Reverb ESP Discharge	X	
			TOTAL ARSENIC OUT	63 + X	lb/hr

Bydifference:
Reverb ESP Discharge = 103 - 63 = 40 lb/hr

ARSENIC DISCHARGE DETERMINED BY DIRECT MEASUREMENT

Smelter personnel measured arsenic emissions during March, 1977 using a filter/impinger train. The arsenic emission values obtained at the ESP outlet were: 25 lb/hr (March 1, 1977), 34 lb/hr (March 2, 1977), and 49 lb/hr (March 3, 1977). Of these emissions, 16, 17 and 23 lb/hr respectively were in the form of gaseous arsenic. Difficulties were encountered during these experiments due to the deposit of a yellow-orange material on the walls of the sampling lines which caused the filter to clog.

On July 11, 1976, the authors used the WEP train to make determinations at the ESP inlet and outlet. These determinations showed arsenic flows of 190 lb/hr at the inlet and 140 lb/hr at the outlet duct indicating an ESP efficiency of 26 percent. A second determination on July 13, using the WEP train showed an emission rate of 76 lb/hr at the ESP outlet.

The modified EPA Method 5 train followed by a set of 6 impingers was used by the authors to collect samples at the inlet and outlet of the ESP on July 13 and July 14, 1976. Arsenic flow rates of 59, 73 and 75 lb/hr giving an average of 69 lb/hr were found at the inlet. The corresponding values at the outlet were 54, 45 and 51 lb/hr or an average of 50 lb/hr. This indicates that an average of 72% of the incoming arsenic is discharged to the stack. These values are slightly higher than the flows determined by material balance difference (44 lb/hr in January and 40 lb/hr in March 1977) and the measurements made by smelter personnel using the filter/impinger train described above.

A summary of all the measured arsenic emission rates from the reverb ESP is as follows:

Jan. 1977 - Mat. balance	- 44 lb/hr	July 1976 - WEP-Imp.	- 140 lb/hr
Mar. 1977 - Mat. balance	- 40 lb/hr	July 1976 - WEP-Imp.	- 76 lb/hr
Mar. 1977 - Filter Imp.	- 25 lb/hr	July 1976 - EPA Meth. 5	- 54 lb/hr
Mar. 1977 - Filter Imp.	- 34 lb/hr	July 1976 - EPA Meth. 5	- 45 lb/hr
Mar. 1977 - Filter Imp.	- 49 lb/hr	July 1976 - EPA Meth. 5	- 51 lb/hr

FLUCTUATIONS OF THE ARSENIC CONCENTRATION IN THE REVERBERATORY FURNACE FEED

The reasons for the varying arsenic emissions are different dust recycling rates and changing As concentrations in the Cu ore. Recycle dust for instance contains 5-10% As. Both factors can lead to wide variations in the reverberatory furnace feed as is shown for the A, B, and C shifts of February 28, 1977 through March 4, 1977:

Date	ppm As in feed	Date	ppm As in feed	Date	ppm As in feed
A 2/28/77	= 1400	B 2/28/77	= 1200	C 2/28/77	= 2900
A 3/1/77	= 3100	B 3/1/77	= 7400	C 3/1/77	= 3100
A 3/2/77	= 1400	B 3/2/77	= 2400	C 3/2/77	= 3300
A 3/3/77	= 3100	B 3/3/77	= 2300	C 3/3/77	= 4000
A 3/4/77	= 1800	B 3/4/77	= 780	C 3/4/77	= 3700

The ESP efficiency for arsenic removal was found to be 26 and 28%. The variation in discharge rates are explainable in the light of the above As variations in the feed which range from 7400 ppm As (B 3/1/77) to 780 ppm As (B 3/4/77).

IDENTIFICATION OF MAJOR CRYSTALLINE SPECIES

X-ray diffraction was used to investigate the nature of the major crystalline phases. The goniometer technique using Cu Kα radiation was applied.

Arsenolite (As_2O_3) was positively identified in the hopper dust. Arsenolite was also present in the material collected by the in-stack filter, the out-of-stack filter, and the impingers used at the ESP outlet. These findings indicate that arsenolite leaves the ESP in both a solid and a gaseous phase.

SUMMARY AND CONCLUSIONS

The data obtained from the reverberatory furnace electrostatic precipitator emission tests can be summarized as follows: 1) Approximately 50 percent of the arsenic entering the green fed reverberatory furnace is fumed off and leaves the furnace in the off-gases; approximately 25 percent leaves the smelter with the reverberatory slag; approximately 25 percent is transported with the matte to the converters. A portion of the arsenic sent to the converters is fumed off and exits the smelter in the sulfuric acid plant blowdown; 2) the arsenic emitted from the reverberatory furnace ESP varies from 25 to 140 pounds per hour; 3) the ESP control efficiency for arsenic is between 26 to 28 percent at 600°F; 4) part of the arsenic escaping the reverb ESP is in the gaseous state; 5) arsenolite, As_2O_3, is the major identified arsenic species emitted. The observed preferrential emission of arsenic in the gaseous streams in this study is the same as that observed at the primary copper smelter in Bor, Jugoslavia (ref 4). Based on these results it can be concluded that the hot ESP's servicing green fed reverberatory furnaces do not effectively control arsenic emissions.

ARSENIC IN URANIUM MILL EFFLUENTS

The summarized data reported above from the PEDCO (1983) report on mine-mill wastes in the U.S.A. indicated that arsenic levels in liquid effluents and seepage from uranium mines in the U.S.A. is likely to be low.

ERGO

Roasted pyrite concentrates produced on the Witwatersrand yield some arsenic in the calcine washwaters. These are treated for effective arsenic removal by the addition of ferric iron (in raffinate) and vigorous aeration agitation with lime to reduce arsenic in solution to below 0.5 ppm As. One such treatment arrangement is briefly described in the Appendix I trip report. More data may be requested from:

KEY LAKE

The very rich uranium deposits is Saskatchewan are characterized by high Ni and Co values, often with high arsenic levels. Two arsenic removal methods are described in Appendix I for KEY LAKE MINING LTD. and for RABBIT LAKE.

The process developed for KEY LAKE arsenic removal and described by CLARKE, et al. (1980) is one in which arsenic is removed with other metals in wastewater and excess minewater by staged addition of lime via flash mixers followed by radium removal by $BaCl_2$ and lime addition again using flash mixers. This process reduces effluents to less than 0.1 ppm As. CLARKE, et al. (1980) found that the higher the pH, the lower the arsenic level that can be achieved as shown in the following diagram.

SHERRITT GORDON MINES LIMITED

This arsenic removal process was believed to be due to extremely low solubilities of $BaRaAsO_4$ which led to patents by SHERRITT GORDON MINES (1980). The chemical basis for the patent has been challenged by ROBINS (1985), but the fact remains that arsenic is removed from the system even if the interpretation of the mechanism is not altogether accurate.

KEY LAKE MINING operations as described by CLARKE, et al. (1980), show how subaerial tailings disposal in layers are extremely impermeable and results in an excellent method of encapsulating the arsenic-rich precipitate sludges generated by the water treatment plant. This circumvents any question about the stability of arsenic precipitates in the presence of CO_2.

The arsenic removal testwork and also the subaerial tailings disposal method was deminstrated for KEY LAKE MINING by:

RABBIT LAKE

At RABBIT LAKE operations, a change in ore type from the RABBIT LAKE ore deposit, which is now exhausted, to the Collins Bay B-Zone ore which has much higher arsenic levels (up to 10% As in the LRC high grade ore), meant that a new process flowsheet had to be installed. Metallurgically, other significant differences were the higher concentrations of nickel, molybdenum, cobalt, as well as arsenic in the Collins Bay B-Zone ore.

Nickel and arsenic solubilize under leaching conditions favorable for uranium, and both of these metals extract in excess of 80%. Major modifications were necessary to the solvent extraction process, to the uranium precipitation process, and to the tailings disposal and effluent treatment processes which are described in the discussion of RABBIT LAKE in Appendix I.

Arsenic is precipitated as ferric arsenate by the addition of ferric sulfate followed by pH controlled addition of slaked lime to an approximate pH of 3.5 and magnesium hydroxide to an approximate pH of 3.8. The solution with precipitate (iron cake) is thickened. The precipitate is leached with pregnant aqueous solution from the leach process for uranium recovery as some uranium is precipitated during the $Mg(OH)_2$ additon step. The ferric arsenate eventually leaves the circuit in the tailing stream from the CCD circuit. Maximum allowable levels of arsenic in the final effluent are 0.5 mg As/l.

Arsenic is precipitated from tailings slurry in the form of ferric arsenate. Barren solution containing the majority of the arsenic is treated separately. The equipment consists of a number of tanks where a 1% mixture of SO_2 from the sulfuric acid plant in air is sparged into the agitated solution to insure that all iron present in the solution is

oxidized to the ferric state. Lime is added to maintain the pH at 1.3. Thereafter, the pH is raised to 4.5 by adding more lime and arsenic precipitates as ferric arsenate. The slurry is thickened to recover solution from where solids are pumped to the first stage in the neutralization circuit. Thickener overflow was planned to be used as CCD wash solution or pumped to the neutralization circuit if its quality is not good enough for CCD washing.

Nickel in the effluent could also be precipitated by further pH adjustment which would further scavenge arsenic from solution.

[57] **ABSTRACT**

A process for removing arsenic from an aqueous solution containing arsenic in the form of a soluble arsenate includes adjusting the pH of the solution if necessary to at least about 10, adding a soluble barium salt to precipitate arsenic as barium arsenate, and removing the precipitated barium arsenate from the solution.

REMOVAL OF ARSENIC FROM AQUEOUS SOLUTIONS

This invention relates to the removal of traces of dissolved arsenic from aqueous solutions to reduce the dissolved arsenic concentration to very low values for example less than 0.5 mg/L.

There are various industrial processes in which a waste aqueous solution contains arsenic whose concentration must be reduced to an extremely low level before the aqueous solution is considered safe for disposal by discharge to the environment. For example, in hydrometallurgical processes for the recovery of metals from their ores, the ore treated often contains arsenic which is dissolved during the hydrometallurgical operation. Although various methods are known for removing some arsenic from solution, known methods which are commercially acceptable are only able to reduce the concentration of dissolved arsenic to about 1 or 2 mg/L. However, environmental regulations in many places do not permit the discharge to the environment of water containing such concentrations of arsenic, but only permit discharge when the arsenic concentration is much lower, for example below 0.5 mg/L.

It is known to precipitate dissolved arsenic as calcium arsenate and/or ferric arsenate, for example by the addition of lime and/or ferric sulphate, in order to reduce the dissolved arsenic content of an aqueous solution from relatively high concentrations down to about 1 or 2 mg/L. However, the solubilities of calcium arsenate and ferric arsenate are such that it is not possible to reduce the dissolved arsenic concentration still further by this method.

The present invention is based on the discovery that the arsenic concentration in an aqueous solution containing dissolved arsenic in the form of a soluble arsenate, such as calcium arsenate and/or ferric arsenate, can be significantly reduced by adjusting the pH of the solution if necessary to at least 10, preferably to 11 or 12, and adding a soluble barium salt, such as barium chloride, to precipitate dissolved arsenic as barium arsentate. In this way, the dissolved arsenic concentration can be reduced to less than 0.5 mg/L and, at the preferred pH of 11 of 12, probably to less than 0.2 mg/L. The soluble barium salt may be added before, during or after the pH adjustment.

Preferably, any pH adjustment is carried out and any precipitate, formed as a result of the pH adjustment, is removed before addition of the soluble barium salt.

The invention may be used to remove dissolved arsenic from an acidic aqueous solution by raising the pH of the solution to at least about 3, preferably at least about 5 and more preferably at least about 7, and adding ions selected from the group consisting of calcium ions and ferric ions if necessary to precipitate some of the arsenic as at least one of the compounds selected from the group consisting of calcium arsenate and ferric arsenate, separating the precipitate from the remaining solution to provide an aqueous solution containing at least one dissolved arsenate selected from the group consisting of calcium arsenate and ferric arsenate, adjusting the pH of the solution if necessary to at least about 10, adding barium chloride to precipitate arsenic as barium arsenate, and separating the precipitated barium arsenate from the solution.

The invention is especially useful in the recovery of uranium from uranium ores which also contain arsenic and iron.

One embodiment of the invention will now be described, by way of example, with reference to the accompanying drawing which shows a flow diagram of a uranium recovery process.

Referring to the drawing, a uranium-bearing ore of a sulphidic nature which also contains arsenic and iron in addition to other impurities is leached in aqueous sulphuric acid solution under oxidizing conditions in leach step 12. The leached slurry is subjected to a liquid-solids separation step 14 where the undissolved residue is removed for disposal as desired, for example by inclusion in the neutralization step which will be described later. The leach solution proceeds to a uranium extraction step 16 where uranium values are extracted from the leach solution, for example by solvent extraction.

The remaining solution containing dissolved arsenic and other impurities including iron then proceeds to a neutralization step 18 where lime is added to raise the pH of the solution to about 11 or 12 to cause precipitation of most of the dissolved impurities. In particular, most of the arsenic precipitates as calcium arsenate and/or ferric arsenate. Oxygen is bubbled into the solution during this step to oxidize any arsenite ions to arsenate ions. As mentioned above, the residue from the liquid-solids separation step 14 may be fed to this neutralization step. The resultant slurry passes to a further liquid-solids separation step 20, from which the solids may be dealt with as desired.

The aqueous liquid leaving the separation step 20 still contains small amounts of various impurities including arsenic as dissolved calcium arsenate and ferric arsenate, the arsenic concentration being about 1 or 2 mg/L. Since this arsenic concentration is too high to permit discharge of the aqueous liquid to the environment, the liquid is treated in an arsenic removal step 22 in accordance with the invention where barium chloride solution is added to precipitate much of the remaining arsenic as barium arsenate. In the arsenic removal step 22, the pH of the liquid is about 11 or 12 as a result of the lime treatment in the neutralization step 18. In this manner, the arsenic concentration is reduced to less than 0.5 mg/L, and can be reduced to as low as 0.1 mg/L.

The precipitated barium arsenate is removed from the liquid in a subsequent liquid-solids separation step 24, and the separated liquid now qualifies as purified water which can be discharged to the environment. The separated barium arsenate can be dealt with as desired.

An example of the invention will now be described.

EXAMPLE

Solution from a uranium extraction step, from which uranium had been extracted by solvent extraction, was treated with lime in a neutralization step to raise the pH to 11.6 and the resultant precipitate was separated from the remaining solution by settling. The concentrations (in mg/L) of various impurities in the solution before and after the neutralization step are shown in Table 1.

TABLE 1

Impurities	Before Neutralization	After Neutralization
Arsenic	1940	1.2
Nickel	2850	0.2
Iron	2680	<0.1

TABLE 1-continued

Impurities	Before Neutralization	After Neutralization
Aluminum	1250	0.4
Magnesium	1180	0.2
Sulphur	13400	550

The arsenic concentration of 1.2 mg/L after neutralization is too high to permit the solution to be discharged to the environment. Different portions of the solution were treated with barium chloride at different concentrations and temperatures. The resultant barium arsenate precipitate was removed in each case by filtration and the arsenic concentrations in the resultant liquids were determined. The results are shown in Table 2.

TABLE 2

Barium Conc.	Temp (°C.)	Initial pH	Final pH	Arsenic Conc.
100	25	11.6	11.5	0.1
200	25	11.6	11.4	0.1
50	50	11.6	11.6	0.1
100	50	11.6	11.2	0.1
200	50	11.6	11.2	0.1

It will be observed that in all these tests the arsenic concentration was reduced to 0.1 mg/L.

Other embodiments and examples will be readily apparent to a person skilled in the art, the scope of the invention being defined in the appended claims.

What we claim as new and desire to protect by Letters Patent of the United States is:

1. A process for removing arsenic from an aqueous solution containing arsenic in the form of a soluble arsenate selected from the group consisting of calcium arsenate and ferric arsenate, comprising ensuring that the pH of the solution is at least about 10, adding a soluble barium salt to precipitate arsenic as barium arsenate, and removing the precipitated barium arsenate from the solution.

2. A solution according to claim 1 comprising ensuring that the pH of the solution is in the range of from about 11 to about 12.

3. A process according to claim 1 wherein the aqueous solution contains at least 1 mg/L dissolved arsenic, and the addition of barium chloride to precipitate barium arsenate reduces the concentration of dissolved arsenic to less than 0.5 mg/L.

4. A process according to claim 1 wherein the aqueous solution contains at least 0.5 mg/L dissolved arsenic, and addition of barium chloride to precipitate barium arsenate reduces the concentration of dissolved arsenic to less than 0.2 mg/L.

5. A process according to claim 1 wherein the soluble barium salt is barium chloride.

6. A process according to claim 1 wherein the pH of the solution is adjusted to at least about 10 from a lower value and any precipitate formed as a result of pH adjustment is separated from the solution before addition of the soluble barium salt.

7. A process for removing dissolved arsenic from an acidic aqueous solution comprising raising the pH of the solution to at least about 3 and adding ions selected from the group consisting of calcium ions and ferric ions to precipitate some of the arsenic as at least one of the compounds selected from the group consisting of calcium arsenate and ferric arsenate, separating the precipitate from the remaining solution to provide an aqueous solution containing at least one dissolved arsenate selected from the group consisting of calcium arsenate and ferric arsenate, ensuring that the pH of the solution is at least about 10, adding barium chloride to precipitate arsenic as barium arsenate, and separating the precipitated barium arsenate from the solution.

8. A process according to claim 7 comprising ensuring that the solution containing at least one dissolved arsenate is in the range of from about 11 to about 12.

9. A process according to claim 7 wherein the solution containing at least one dissolved arsenate contains at least 1 mg/L dissolved arsenic and the addition of barium chloride to precipitate barium arsenate reduces the concentration of dissolved arsenic to less than 0.5 mg/L.

10. A process according to claim 7 wherein the solution containing at least one dissolved arsenate contains at least 0.5 mg/L dissolved arsenic, and the addition of barium chloride to precipitate barium arsenate reduces the concentration of dissolved arsenic to less than 0.2 mg/L.

11. A process according to claim 7 wherein the pH of the acidic aqueous solution is raised to at least about 5 to precipitate some of the arsenic.

12. A process according to claim 7 wherein the pH of the acidic aqueous solution is raised to at least about 7 to precipitate some of the arsenic.

13. A process according to claim 7 including supplying oxygen to the acidic aqueous solution during the first mentioned arsenate precipitation step to oxidize arsenite ions to arsenate ions.

14. A process according to claim 7 wherein the pH of the solution containing at least one dissolved arsenate is adjusted to at least about 10 from a lower value and any precipitate formed as a result of pH adjustment is separated from the solution before addition of the soluble barium salt.

ARSENIC PRECIPITATE DISPOSAL

Disposal of arsenic precipitate ranges from the most expensive approach of shipping it in a dewatered, packaged form to a hazardous waste disposal site hundreds of miles away to simply decanting water from the precipitate in exposed settling ponds which are used to accumulate the precipitates.

Arsenic precipitate disposal:

CHEM. SECURITY SYSTEMS

ROBINS (1985) and ROBINS and TOZAWA (1982), as mentioned, express concern for the stability of arsenic precipitates in water exposed to the air due to CO_2 destabilization of the precipitate liberating arsenic back to solution with time. However, since numerous other metals are co-precipitated, the stabilities of the precipitate may well be much greater to CO_2 than indicated on the basis of the above laboratory experiments.

EQUITY SILVER MINES (1985) has developed a simple direct lime addition process to precipitate arsenic as ferric arsenate. By blending the precipitate back with the tailings slurry which has excess alkalinity, a waste that meets British Columbia criteria for exemption from the Special Wastes Act is demonstrably achieved.

One of the most innovative and effective arsenic precipitate disposal methods is the encapsulation technique practiced at the KEY LAKE MINING CORPORATION which was developed by:

ABSTRACT

The stability of calcium arsenate is discussed in relation to the possible misuse of lime in the treatment of gold processing waste waters. Stability diagrams have been derived and experimental results cited to show that calcium arsenate has a higher solubility in neutral to alkaline solution than has previously been recognized and this solubility is further enhanced by the presence of carbon dioxide, bicarbonate or carbonate.

Introduction

The removal of arsenic from gold mine waste waters has been of interest[1] for more than thirty years, but with the recent emphasis on clean water standards there has been renewed activity in relation to that problem[2,3,4,5]. The processing of gold-bearing sulphides which contain arsenopyrite and other complex arsenic sulphides is well established. Initial roasting to oxidize the sulphides leaves the arsenic in the form of both arsenic (III) and arsenic (V), in which forms it is soluble in the subsequent leaching stage. Further oxidation of the leach liquors is required[5] before the well-established procedure of precipitating calcium arsenate with lime, which is carried out despite an immense lack of knowledge of the calcium-arsenic-water system.

The solubility product and free energy of formation for $Ca_3(AsO_4)_2$, which are to be found in recent and reliable sources of data[6,7], originate from the work of Chukhlansev[8], whose experimental determination of the concentration of calcium from the solubility of calcium arsenate in solutions of various pH yields the results plotted in Figure 1. This is the work which has resulted in a wide acceptance of the "insolubility" of calcium arsenate and the use of lime to stabilize arsenic in that form.

Laguitton[9] attempted to further elucidate the chemistry of the lime addition method for treating arsenical waste waters from gold processing operations. The low solubility product for $Ca_3(AsO_4)_2$ was the basis for his examination of likely chemical equilibria in the system. Laguitton and other workers[10,11] have not considered atmospheric carbon dioxide as an important component in this system.

The Solubility of Calcium Arsenate

Tozawa, Umetsu and Nishimura[12] further investigated the solubility of calcium arsenate over a wide range of pH by measuring both calcium and arsenic concentrations in solution. Their results, which are plotted in Figure 2, show the trend toward a minimum concentration of both calcium and arsenic at about pH 11, but with the arsenic concentration approximately sixteen times (stoichiometric) that for calcium. These results were interpreted by Robins[13] using ther-

R.G. Robins

Bob Robins is Associate Professor in Chemical Engineering in the School of Chemical Engineering and Industrial Chemistry at the University of New South Wales, Sydney, Australia. Dr. Robins received his B.Sc. and M.Sc. degrees in chemical engineering in 1953 and 1955 and a Ph.D. degree in metallurgy in 1958 from The University of New South Wales. He carried out post-doctoral work at the U.K. Atomic Energy Research Establishment, Harwell, from 1958 to 1961 and then became a Senior Lecturer in Metallurgy at Wollongong University.

Dr. Robins' research activities over the past 20 years have been related to aqueous process development, particularly associated with hydrometallurgical processes. Recently, he was awarded the 1982 Extractive Metallurgy Science Award by the Metallurgical Society of AIME for his work on the solubility of metal arsenates.

K. Tozawa

Kazuteru Tozawa is Professor of Metallurgy and in charge of the Hydrometallurgy Research Division of the Research Institute of Mineral Dressing and Metallurgy (SENKEN), Tohoku University, Sendai, Japan. Professor Tozawa graduated from the Department of Metallurgical Engineering, Tohoku University, in 1948 and then joined the Akita Mining College as Assistant Professor and worked there for 23 years. He obtained the degree of Doctor of Engineering in 1968 for the thesis entitled "Fundamental Research on Pressure Hydrometallurgical Treatment of Complex Sulphide Ores". In 1972, he transferred from Akita University to his present position.

His current interests include the recovery of values from metallurgical intermediates, zinc hydrometallurgy and the problems associated with arsenic residuals from metal extraction processes.

Keywords: Mineral processing, Gold processing, Waste waters, Arsenic removal, Lime, Calcium arsenate.

FIGURE 2. Calcium and arsenic analyses from the determination of calcium arsenate solubility by Tozawa, Umetsu and Nishimura[12].

modynamic equilibrium calculations and a presentation in the form of stability diagrams.

Robins suggested that the results of Tozawa, Umetsu and Nishimura were influenced by the presence of carbon dioxide in the atmosphere ($P_{CO_2} = 10^{-3.52}$ ats.), which causes a reduced stability of calcium arsenate and its decomposition into calcium carbonate. This proposition has much greater significance as carbon dioxide pressures or dissolved carbonate concentrations are increased. The stability diagrams which supported this explanation of the work of Tozawa *et al.* are further modified in this paper by considering the formation of the calcium carbonate complexes $CaCO_3^o$ and $CaHCO_3^+$ in aqueous solution, which leads to a closer agreement between experimental and predicted stability.

Stability Diagrams for Calcium Arsenate - Carbonate - Water

The derivation of log activity versus pH diagrams is based on a consideration of all of the known and likely reactions in the particular system in the general form:

$$aA + xH^+ = bB + cH_2O$$

and a calculation of equilibrium from the standard reaction isotherm

$$\Delta G^o = -R\,T \ln K$$

expanded by taking T = 298.15, pH = $-\log a_{H^+}$ and $a_{H_2O} = 1$, to obtain the equation

$$xpH = \frac{-\Delta G^o}{1.364} - \log \frac{a_B^b}{a_A^a}$$

which results in a series of straight lines which delineate the stability regions for the compounds and ions considered on a plot of log activity versus pH.

Stability diagrams for the calcium arsenate - carbonate - water system were calculated using the free energy data (listed in Table 1), taken mostly from NBS Technical Note 270[7]. The equilibria considered are set out as follows:

$H_3AsO_4^- + H^+ = H_3AsO_4$ ..... (1)
$HAsO_4^{2-} + H^+ = H_2AsO_4^-$ ..... (2)
$AsO_4^{3-} + H^+ = HAsO_4^{2-}$ ..... (3)
$CaOH^+ + H^+ = Ca^{2+} + H_2O$ ..... (4)
$Ca(OH)_2^o + H^+ = CaOH^+ + H_2O$ ..... (5)
$Ca(OH)_2 + 2H^+ = Ca^{2} + 2H_2O$ ..... (6)
$Ca(OH)_2 + H^+ = CaOH^+ + H_2O$ ..... (7)
$Ca(OH)_2 = Ca(OH)_2^o$ ..... (8)
$Ca_3(AsO)_2 = 2H_2AsO_4^- + 3Ca^{2+}$ ..... (9)
$Ca_3(AsO_4)_2 + 2H^+ = 2HAsO_4^{2-} + 3Ca^{2+}$ ..... (10)
$Ca_3(AsO_4)_2 = 2AsO_4^{3-} + 3Ca^{2+}$ ..... (11)
$Ca_3(AsO_4)_2 + 3H_2O = 2AsO_4^{3-} + 3CaOH^+ + 3H^+$ .. (12)
$Ca_3(AsO_4)_2 + 6H_2O = 2AsO_4^{3-} + 3Ca(OH)_2 + 6H^+$. (13)
$H_2CO_3 = CO_2 + H_2O$ ..... (14)
$HCO_3^- + H^+ = H_2CO_3$ ..... (15)
$CO_3^= + H^+ = HCO_3^-$ ..... (16)
$CaCO_3 + H^+ = Ca^{2+} + HCO_3^-$ ..... (17)
$CaCO_3 + 2H^+ = Ca^{++} + H_2CO_3$ ..... (18)
$CaCO_3 + H^+ = CaHCO_3^+$ ..... (19)
$Ca_3(AsO_4)_2 + 3HCO_3^- = 3CaCO_3 + 2HAsO_4^{2-} + H^+$. (20)
$Ca_3(AsO_4)_2 + 3CO_3^{2-} + 2H^+ = 3CaCO_3 + 2HAsO_4^{2-}$ ..... (21)
$Ca_3(AsO_4)_2 + 3H_2CO_3 = 3CaCO_3 + 2H_2AsO_4^- + 2H^+$. (22)
$Ca(OH)_2 + CO_3^{2-} + 2H^+ = CaCO_3 + 2H_2O$ ..... (23)
$Ca^{++} + HCO_3^- = CaHCO_3^+$ ..... (24)

The stability diagrams presented here in Figures 3 to 6 show that calcium arsenate is more soluble than is widely accepted, particularly in relation to the treatment of gold processing waste waters. This is substantiated to some extent by experimental solubility determinations[12], but it is obvious that further verification is required. An attempt has been made here to take into account all of the reactions which could influence the solubility of calcium arsenate, and Figures 3-5 are drawn for the case of equal activities of calcium and arsenic. Figure 6 is a three-dimensional diagram showing the effects of calcium and arsenic independently. Only one calcium arsenate, $Ca_3(AsO_4)_2$, is considered in this work, although several other calcium-arsenic (v) compounds have been reported in the literature[13]. It is therefore stressed that the considerations presented here relate to a simple system which in fact may not

FIGURE 7. Stability regions for metal arsenates in water influenced by carbon dioxide in the atmosphere ($P_{CO_2} = 10^{-3.52}$ ats.).

take into account all of the chemical factors which should be considered in the disposal of arsenic. Also, in the real situation, adsorption and organic complexing are likely to be of importance.

However, if the solubility of a particular metal arsenate is taken as the criterion for stabilization of arsenic residues, then it would appear that certain metal arsenates other than calcium would be more appropriate. Figure 7 shows the stability regions for a number of metal arsenates under the influence of atmospheric carbon dioxide ($p_{CO_2} = 10^{-3.52}$ ats). The comparative insolubility of several arsenates (Pb, Cu, Cd, Ni, Zn) shown here may explain why the disposal of mineral processing arsenical wastes is reasonably effective, and may depend on traces of these metals rather than on calcium. The suggestion[9] that phosphate in the lime system would further help to stabilize arsenic is correct in terms of thermodynamic stability (as well as having experimental support), but there is also the same problem of conversion of phosphate to carbonate under the influence of carbon dioxide in alkaline conditions. There have been other methods proposed by Miyamoto, Suginohara and Yaganase[16,17] for the removal of arsenic from waste waters, but these too would appear to be influenced by the effects of carbon dioxide.

The problem of stabilizing arsenic is one which needs further investigation, initially at the fundamental level of determining experimental solubilities of metal arsenates and as well the possible existence of metal double-salt arsenates. Also, in view of the oxidation stability of arsenic (III), the solubilities of arsenities should be determined. These studies are currently in progress in the laboratories of both of the authors.

The Solubility of Barium Arsenate: Sherritt's Barium Arsenate Process

R.G. ROBINS

In August 1980 a paper[1] entitled "The Key Lake Uranium Process" was presented at the 19th Annual Conference of Metallurgists of the Canadian Institute of Mining and Metallurgy at Halifax, Nova Scotia. The pre-printed paper described in detail the extraction of uranium at Key Lake in Northern Saskatchewan and was prepared jointly by authors from Key Lake Mining Corporation and Sherritt Gordon Mines Limited. Part III of the paper covers the area of waste control and by-product recovery and on pages 90-91 is a short section on arsenic removal showing effluent pH and arsenic concentrations after barium chloride addition. It is stated that arsenic is precipitated as barium arsenate according to the equation

$$Ca_3(As\ O_4)_2 + 3\ Ba\ Cl_2 \rightarrow Ba_3(AsO_4)_2 + 3CaCl_2$$

and further that the literature[2] reports barium arsenate as the least soluble arsenate with a solubility product of $8x10^{-51}$ which is significantly lower than those for calcium arsenate (3×10^{-19}) and ferric arsenate (6×10^{-21}). The original source of this data is the work by Chukhlansev[3,4] in 1956, where the solubility of many metal arsenates has been determined.

The Sherritt process for removing arsenic (v) from solution with barium chloride or a soluble barium salt was patented in Canada[5] with a priority date of 22nd August 1980. Similar patents have been granted in other countries including U.S.A.[6], but in Australia, Australian Patent Application No. 73159/81 has not yet been examined.

The Sherritt Patent is obviously based on the solubility data for $Ba_3(As_3O_4)_2$ originating from Chukhlansev's work.

There is other perhaps more readily available data[7] for a range of barium arsenate compounds which originate from Guerin's work[8] published in 1938. The solubility of $BaH\ AsO_4$ reported by Guerin at pH = 7 is five orders of magnitude higher than that which can be obtained by extrapolating Chuklansev's solubility of "$Ba_3(AsO_4)_2$" obtained at pH = 2-3 up to pH = 7. This inconsistency led the author to obtain independent solubility data by mixing solutions of 0.1 M H_3AsO_4 and 0.1 M $Ba(OH)_2$ adjusted to various pH levels with perchloric acid to obtain precipitates of the two arsenates $BaH\ AsO_4$ and $Ba_3(AsO_4)_2$ which were stable over the pH range 5-12. The solutions which remained in contact with the precipitates after several weeks of mixing under an atmosphere of high purity nitrogen (to exclude atmospheric carbon dioxide) were analysed for barium using the barium o-cresolphthalein complexone method and turbidimetric analysis as the sulphate, and arsenic using the silver diethyldithiocarbamate complex in pyridine. The results were consistent with Guerin's data (see Figure 1). All experiments were performed in a laboratory which is controlled at 25°C.

The solubility of the two barium arsenates can be described by the following equations:

R.G. ROBINS is Associate Professor, School of Chemical Engineering and Industrial Chemistry, the University of New South Wales, Kensington, N.S.W. 2033, Australia.

Manuscript Received . 1984.

(1) $\underline{Ba\ H\ AsO_4}$

In the pH range 5.0 - 6.76

$Ba\ H\ AsO_4 + H^+ = Ba^{2+} + H_2AsO_4^-$

$pH = 1.22 - \log Ba^{2+} - \log H_2AsO_4^-$

In the pH range 6.76 - 9.3

$Ba\ H\ AsO_4 = Ba^{2+} + H\ As\ O_4^{2-}$

$\log H\ AsO_4^{2-} = -5.54 - \log Ba^{2+}$

(2) $\underline{Ba_3(AsO_4)_2}$

In the pH range 9.3 - 11.6

$Ba_3(As\ O_4)_2 + 2H^+ = 3Ba^{2+} + 2HAsO_4^{2-}$

$pH = 2.60 - \frac{3}{2} \log Ba^{2+} - \log H\ AsO_4^{2-}$

From the above experimental equations the free energies of formation of the two barium arsenate compounds can calculated:

$BaH\ AsO_4$: $\Delta G^o_{f,298.15} = -1307$ kJ

$Ba_3(AsO_4)_2$: $\Delta G^o_{f,298.15} = -2521$ kJ

These compounds are similar to those in the calcium-arsenic (v)- water system which has been studied by Nishimura Tozawa and Robins[9], in which the effect of atmospheric carbon dioxide at pH > 8.1 is to cause decomposition of calcium arsenate to calcium carbonate. This reaction which was predicted by the author[10] has caused some concern about the efficacy of stabilizing arsenical wastes with lime.

In the case of the barium arsenates, it can also be shown theoretically that at pH > 8.3 in the presence of atmospheric carbon dioxide the carbonate will be formed. The author has aerated slurries of $Ba_3(AsO_4)_2$ (pH = 11.6) to prove the reaction

$$Ba_3(AsO_4)_2 + CO_2 + H_2O = BaCO_3 + 2Ba\ H\ AsO_4$$

which drops the pH to 8.3 where the arsenic solubility is about 135 mg/l.

The author has also investigated the magnesium-arsenic (v)-water system and a comparison of the solubilities of calcium, magnesium and barium arsenates is presented in Figure 2. It is obvious from this figure that barium arsenate offers little advantage for removing arsenic as a stable and highly insoluble material.

The Sherritt patent claims the use of barium chloride or a soluble barium salt at a pH of at least 10 but preferably 11 or 12 to precipate arsenic and the removal of the precipitated barium arsenate from solution.

The solubility of barium arsenate, $Ba_3(AsO_4)_2$, in the absence of carbon dioxide is approximately 75 mg/l at pH 10, 40 mg/l at pH 11 and 10 mg/l at pH 12. In the presence of the carbon dioxide in atmospheric air ($p_{CO_2} = 10^{-3.47}$ atmospheres) barium arsenate is unstable above pH 8.3.

It appears that there is no chemical solubility basis for the Sherritt Patent, and that in the Key Lake effluents some other chemical or physical factor apart from the solubility of barium arsenate is responsible for low arsenic levels.

Ackhowledgement. This work is part of a project on the stability of arsenic compounds which is supported by the Australian Mineral Industries Research Associated Limited.

CHAPTER 30

BARIUM Ba

Barium in solution is acutely toxic to humans and aquatic life.

Fortunately, because barium sulfate has an extremely low solubility in water at all pH's, soluble barium is most unlikely to occur in mine and mill effluents. There is almost always adequate sulfate available in water to quantitatively remove Ba^{+2} from solution to a level of insignificance.

The need to remove Ba from solution was not once encountered. In fact, $BaCl_2$ addition is used as a treatment process for the removal of radium from uranium mine and mill effluents.

CHAPTER 31

BERYLLIUM Be

Beryllium oxide is very toxic to humans when inhaled, and beryl mineral processing plants must use special precautions.

Soluble beryllium is seldom encountered in mine-mill environments and, in this investigation, no cases were encountered where beryllium has to be removed from effluents.

A major source of Be to the aquatic environment is the burning of fossil fuels, especially coal, according to TEPPER (1972).

A source of soluble beryllium would be expected to be effluents from Cu-Be metal alloyers, for example, from beryl processors, or acid mine drainage from beryl quarries in pegmatite belts.

Inadequate information is available on the occurrence of beryllium in water and on its toxicity effects.

Little information was found during this investigation on the technology for beryllium removal from water. The EPA (1981) Treatability Manual reports limited information on Be removal in which sodium carbonate precipitation was able to remove 75% of the Be content of an effluent to between 0.1 and 11 ppb. Combined precipitants were able to remove up to 99% of Be down to the detection limit of Be. Unfortunately, the removal processes are not referenced to be able to find the installation, and no details are provided on how Be was precipitated to make this information more useful than a guide to what process might be tried.

ENVIRONMENT PROTECTION CRITERIA

U.S. EPA (1976) established criteria for total beryllium in fresh water to be 11 ug Be/l for soft water with less than 75 mg/l hardness, and 1,000 ug/l Be for hard water with in excess of 75 mg/l total hardness. Ontario (1978) established the same criteria as EPA (1976).

In marine environments, levels of less than 100 ug/l Be was found to present minimal risk to marine organisms.

Beryllium has been found to be acutely toxic to aquatic life at concentrations as low as 5.3 ug/l for D. magna. According to the EPA Treatability Manual, Be is chronically and acutely toxic to freshwater aquatic life at 130 and 5.3 ug/l respectively, and some species are expected to be even more sensitive. Hardness has a big effect on toxicity.

For maximum protection of human health from the carcinogenic effects of beryllium in water and contaminated aquatic organisms, the ambient water concentration should be zero based on the non-threshold assumption for Be. Since zero level is not attainable, a criteria in the parts per trillion range has been suggested.

VOGEL (1961) discusses some basic chemistry methods for separating beryllium from solutions on a laboratory scale. It may be precipitated with aqueous ammonia solution in the presence of ammonium chloride or nitrate. The precipitate is gelatinous and has a tendency to adsorb onto glass and may adsorb other species. It may be precipitated together with aluminum hydroxide which it resembles in many respects. Beryllium may also be precipitated as beryllium ammonium phosphate.

CHAPTER 33

BORON B

Boron does not appear to be a common problem in mine-mill effluents, and no information was gathered about regulatory criteria for this element or borate BO_3^- ions which is its most common form in nature.

Borates do occur in some western waters and have been observed precipitating from geothermal water springs located just north of Lake Beryessa, California.

HOMESTAKE's NPDES permit for the McLaughlin project states that any discharges shall not cause a statistically significant, incremental increase of more than 10% over upstream levels of the receiving waters for mercury, chromium, cadmium, boron, copper, and nickel. Their permit allows discharge of water from sedimentation ponds installed to remove sediments from collected drainage water from the site. Discharge of process effluent is not permitted for this zero discharge operation.

Information on industrial waste levels of boron and on treatment processes for its removal is scarce. Boron levels up to 5.5 mg/l have been reported in raw sewage by WAGGOTT (1969).

A major source of boron in this wastewater is sodium perborate which is used as a bleach in washing powders.

Fluoborate solutions are also used in plating cadmium, copper, lead, nickel, tin, and zinc according to LOWE (1970) up to 125,000-265,000 mg/l.

REMOVAL OF BORATES AND BORON FROM WATER

PATTERSON (1975) found few techniques for the removal of boron from aqueous solutions. A patented process (DOELDNER, 1970) using VCE does not appear to be very effective in that water recovered from a waste containing 20,000 ppm boron still contained around 50 mg/l B. After passing the water through a 6-foot reflux column, the boron level dropped to 2 ppm.

WAGGOTT (1969) reported the failure of several common water treatment processes to remove boron. The conventional biological waste treatment process has no effect on boron levels in domestic sewage. Lime, aluminum, and ferric sulfate coagulants up to dosages of 400, 100, and 100 mg/l are also ineffective. In one reverse osmosis test reported by PATTERSON (1975) only 10% of the total boron was removed from the wastewater.

WILMOTH, et al. (1979) tested lime neutralization reverse osmosis and ion exchange for their effectiveness in removing ten trace elements from acid mine drainage. Lime neutralization was ineffective in removing boron. Two bed (strong acid-weak base) ion exchange systems were ineffective in removing P and B, but apparently reverse osmosis removed an unspecified amount of Boron.

CRUVER (1973) found that reverse osmosis using a cellulose acetate membrane at pH 5 can remove 38-65% of boron in feedwater. R.O. treatment of brackish groundwater with 0.35 ppm B achieved a level of 0.14 mg/l B in permeate and 0.4 mg/l in the concentrate which works out at 60% rejection rate by the cellulose acetate membrane.

FLETCHER (1971) has described a commercially available solvent extraction reagent from the DOW CHEMICAL CO. which is used for boron extraction from brines, but SX usually would not be economical down to ppm levels in effluent treatment.

MAVIS (1984, personal communication) is aware of only two plants in the world where boron is selectively removed from water by ion exchange. A Rohm and Haas resin is used, and the process is reputedly very expensive. More information may probably be available from:

CH2M HILL, INC.

PATTERSON (1975) and KUNIN, R., (1973) refer to a Rohm and Haas ion-exchange resin, IRA-943, which is highly selective for the removal of boron as borate and boric acid which is not interfered with by the presence of other inorganic salts. For solutions containing ten mg/l boron, levels down to one mg/l were achieved. Removal efficiency is dependent on the flow rate through the column.

According to CALMON (1974), the 1974 costs of removing boron by ion exchange was $0.12-$0.30/1000 gallons.

MAVIS (1984, personal communication) referred to the increased efficiency of ion exchange removal of boron in the presence of F^- ions, apparently in the form of BF_4.

HOLM AND SIMPSON (1984) describe an acid mine drainage treatment demonstration using the Wannamaker continuous concentrator which is a simplified version of a cross-flow

micro filter in which the solids fraction are recirculated through a porous fire-hose type textile allowing the filtrate to pass through. Although in the treatment of the Argo tunnel and mine drainage described, boron removal is not considered a factor, the developers of the equipment claim that the Wannamaker Continuous Concentrator can be used for the removal of boron from municipal and other water. The people involved decline to divulge details of the equipment but are prepared to act as consultants:

CHAPTER 32

BISMUTH Bi

Bismuth is rarely found in minewater or metallurgical solutions. No case was encountered where bismuth is included in the list of metals to be analyzed for and reported in mine-mill effluents; but an exhaustive search was not made.

No data was found on the health effects of bismuth on humans or aquatic species, although the use of Pepto Bismol containing bismuth as a medicine is noted.

No effluent criteria for Bi in fresh or marine effluents were found.

MENNE (1984, personal communication) noted one case where the presence of Bi in a gold ore interfered with carbon absorption of gold from a cyanided pulp. At RIO TINTO's Renco operation in Zimbabwe described by RANDOL (1981). After CIP recovery of gold, a flotation concentrate is recovered containing .26% Cu and 1,000 g Bi/t. Bi absorbed on the carbon surface and depressed the gold absorption characteristics. Nonetheless, the Renco CIP plant has operated very satisfactorily despite the bismuth occurrence.

In RANDOL (1981), a description of the Athens mine of LONRHO in Zimbabwe revealed that they, too, experience a problem with gold absorption from the cyanided leach pulp with gold recoveries of only 60-85% and barrens solution of around 1 ppm in tailings pulp. It is noted that bismuth occurs in the ore which is dissolved, absorbed on carbon, desorbed, and also partially removed from the steel wool cathodes by washing. The cathode acid solution contained 1,000 ppm Bi. It is surmized that bismuth may be the cause of the carbon absorption problem experienced by LONRHO at Athens.

It is concluded that not enough information is available on health and environmental effects or on the metallurgical effects of bismuth when it occurs in metallurgical solutions.

Cadmium is one of the greater nuisances environmentally for mine-mill operators. It is toxic to humans and to aquatic life at very low levels and is mobile. Regulatory criteria in the U.S.A. and Canada for fresh water discharge at no more than 0.2 ug/l Cd are both difficult to attain and difficult to determine analytically. The environmental justification for such a low-level limit for Cd is controversial. An important observation is that effective filtration is a necessary polishing step to achieve 1 ppb Cd levels.

INTRODUCTION OF CADMIUM TO THE ENVIRONMENT

Potential sources of Cd in wastewaters include metallurgical alloying, ceramics manufacture, electroplating, inorganic pigments, textile printing, and mine drainage according to McKEE and WOLF (1963), SANTIANELLO (1971), and PATTERSON (1975). Reported instances of high concentrations of cadmium in plating wastes and mine drainage were levels of 1,000 ug Cd/l were found by McKEE and WOLF (1963) and of 440-100 ug Cd/l by LARSEN, et al. (1973).

FULKERSON and GOELLER, Eds., (1973) prepared a massive document under a National Science Foundation RANN program grant as part of the Oak Ridge National Laboratory - NSF Environmental Program titled "Cadmium - The Dissipated Element" which provides copious data on cadmium and its environmental effects including a map of the U.S.A. showing zinc-cadmium producing facilities.

There are no known mines which produce Cd as the primary product. Cadmium frequently occurs with zinc, lead, and copper ore deposits as a minor constituent and is concentrated with these metals in the sulfide flotation process. In the treatment of these concentrates, cadmium is volatilized in the roasting and sintering steps and is further concentrated in fluedusts, particularly if these are recycled in the process. Prior to the need to clean stack gases, cadmium would be widely distributed around smelter and refinery sites as a result of fallout from stack gases from such facilities. Seepage from accumulated piles of pyrometallurgical plant residues to the inevitable nearby stream presents(ed) one pathway for cadmium to enter receiving waters.

In modern base metal smelters and refineries, the main pathway appears to be through liquid effluents from the process and plant runoff after appropriate treatment, and the introduction of Cd to aqueous environment from this source has been greatly reduced. Recycling of water, however, can result in increased Cd levels in effluent bleeds.

In the U.S.A., several abandoned or no longer operating zinc mine and refinery sites have been designated superfund sites because of metal (including Cd) leakages to nearby streams.

CHAPTER 33

BORON B

Boron does not appear to be a common problem in mine-mill effluents, and no information was gathered about regulatory criteria for this element or borate BO_3^- ions which is its most common form in nature.

Borates do occur in some western waters and have been observed precipitating from geothermal water springs located just north of Lake Beryessa, California.

HOMESTAKE's NPDES permit for the McLaughlin project states that any discharges shall not cause a statistically significant, incremental increase of more than 10% over upstream levels of the receiving waters for mercury, chromium, cadmium, boron, copper, and nickel. Their permit allows discharge of water from sedimentation ponds installed to remove sediments from collected drainage water from the site. Discharge of process effluent is not permitted for this zero discharge operation.

Information on industrial waste levels of boron and on treatment processes for its removal is scarce. Boron levels up to 5.5 mg/l have been reported in raw sewage by WAGGOTT (1969).

A major source of boron in this wastewater is sodium perborate which is used as a bleach in washing powders.

Fluoborate solutions are also used in plating cadmium, copper, lead, nickel, tin, and zinc according to LOWE (1970) up to 125,000-265,000 mg/l.

REMOVAL OF BORATES AND BORON FROM WATER

PATTERSON (1975) found few techniques for the removal of boron from aqueous solutions. A patented process (DOELDNER, 1970) using VCE does not appear to be very effective in that water recovered from a waste containing 20,000 ppm boron still contained around 50 mg/l B. After passing the water through a 6-foot reflux column, the boron level dropped to 2 ppm.

WAGGOTT (1969) reported the failure of several common water treatment processes to remove boron. The conventional biological waste treatment process has no effect on boron levels in domestic sewage. Lime, aluminum, and ferric sulfate coagulants up to dosages of 400, 100, and 100 mg/l are also ineffective. In one reverse osmosis test reported by PATTERSON (1975) only 10% of the total boron was removed from the wastewater.

WILMOTH, et al. (1979) tested lime neutralization reverse osmosis and ion exchange for their effectiveness in removing ten trace elements from acid mine drainage. Lime neutralization was ineffective in removing boron. Two bed (strong acid-weak base) ion exchange systems were ineffective in removing P and B, but apparently reverse osmosis removed an unspecified amount of Boron.

CRUVER (1973) found that reverse osmosis using a cellulose acetate membrane at pH 5 can remove 38-65% of boron in feedwater. R.O. treatment of brackish groundwater with 0.35 ppm B achieved a level of 0.14 mg/l B in permeate and 0.4 mg/l in the concentrate which works out at 60% rejection rate by the cellulose acetate membrane.

FLETCHER (1971) has described a commercially available solvent extraction reagent from the DOW CHEMICAL CO. which is used for boron extraction from brines, but SX usually would not be economical down to ppm levels in effluent treatment.

MAVIS (1984, personal communication) is aware of only two plants in the world where boron is selectively removed from water by ion exchange. A Rohm and Haas resin is used, and the process is reputedly very expensive. More information may probably be available from:

PATTERSON (1975) and KUNIN, R., (1973) refer to a Rohm and Haas ion-exchange resin, IRA-943, which is highly selective for the removal of boron as borate and boric acid which is not interfered with by the presence of other inorganic salts. For solutions containing ten mg/l boron, levels down to one mg/l were achieved. Removal efficiency is dependent on the flow rate through the column.

According to CALMON (1974), the 1974 costs of removing boron by ion exchange was $0.12-$0.30/1000 gallons.

MAVIS (1984, personal communication) referred to the increased efficiency of ion exchange removal of boron in the presence of F^- ions, apparently in the form of BF_4.

HOLM AND SIMPSON (1984) describe an acid mine drainage treatment demonstration using the Wannamaker continuous concentrator which is a simplified version of a cross-flow

micro filter in which the solids fraction are recirculated through a porous fire-hose type textile allowing the filtrate to pass through. Although in the treatment of the Argo tunnel and mine drainage described, boron removal is not considered a factor, the developers of the equipment claim that the Wannamaker Continuous Concentrator can be used for the removal of boron from municipal and other water. The people involved decline to divulge details of the equipment but are prepared to act as consultants:

CADMIUM

Acid mine drainage from numerous abandoned base metal mines and tailings impoundments represents a source of uncontrolled Cd loss to the environment.

During this investigation, it was found that some base metal mines, mills, and refineries "do not have" Cd associated with their effluents. Others clearly do, yet have the cadmium situation under such tight control that it does not appear on their list of elements analyzed in their effluent monitoring program. The following table shows a summary of Cd in effluents before and after treatment as encountered in this investigation (see trip reports in Appendix I) and reported in the literature. A second table is provided which summarizes the PEDCO (1984) data on analyses in mine and mill waste materials in the U.S.A.

An interesting aspect of the PEDCo report is that very few of the mine and mill tailings and solutions had cadmium in excess of detection limits of the analysis methods used. The acetic acid EP leach test leaches very little cadmium from mineral wastes that contain cadmium as can be noted in the table summary.

Tailings pond liquid ranged from 4.1 mg/l and 0.190 mg/l Cd for a lead zinc mine (No. 37) and copper mine (No. 31) to less than 0.008 mg/l which was the level often found. In only one case did tailings pond liquid exceed 1 ppm, and in only two cases did it exceed 0.10 ppm. Similarly, untreated minewater was all less than 0.010 mg/l except one molybdenum mine effluent at 0.43 ppm Cd and one lead zinc mine at 0.19 ppm.

Surprisingly, one Idaho phosphate mine (No. 5) had 65.390 ppm Cd in the tailings settled solids which yielded the highest EP leach test result of 0.43 ppm--all the other EP leach tests of settled tailings solids were less than 0.040 ug/g.

Based on the PEDCo data, it would be concluded that cadmium rarely occurs in significant quantities in mine-mill operations and is likely to be located around smelters and roasting plants if at all. The locations of major lead, zinc-lead, and lead-zinc ores as at 1972, i.e., shown in the diagram, bearing in mind that many of these operations have shut down since then due to contraction of the U.S. base metal mining and refining industry. It is around these locations, however, that cadmium may possibly occur in effluents.

REGULATORY EFFLUENT LIMITS - CADMIUM

Regulatory limits for Cd in effluents vary considerably and are controversial in that proposed levels and objectives are very much lower than what is actually enforced in permits of operating mines.

The U.S. EPA (1980) objective and maximum permissible limit for Cd are considerably more lenient for hard water than for soft water as shown in the graph below from the

U.S. EPA (1980). In fact, the EPA 1980 criteria and maximum allowable is a logarithmic function of hardness. In 1984, New York state was proposing to enforce a standard of cadmium on similar lines which involves more than simple mathematics to determine.

Cd Max. = Exp (1.16 [ln hardness ppm] - 6.14)

This works out at follows:

Hardness	50	100	200 mg/l
Maximum Cd Allowed	0.2	0.45	20 mg/l

Persuant to Section 304(a) (1) of the Federal Clean Water Act, the U.S. EPA developed water quality criteria for Cd. For freshwater aquatic life, the total recoverable cadmium criterion is given by e(1.05[ln(hardness)]-8.53) as a 24-hour average with a maximum at any time of e(1.05[ln hardness]-3.73).

This works out as follows in mg Cd/l in ppb (ug/l):

Hardness As $CaCO_3$ mg/l	Total Recoverable 24-Hours	Total Recoverable Grab
50	0.12	1.5
100	0.025	3.0
200	0.051	6.3

In seawater, the criterion developed by the EPA to protect saltwater aquatic life is 4.5 ug/l as the 24-hour average, and 59 ug/l not to be exceeded at any time.

The existing drinking water standard for Cd is 10 ug/l (0.010 ppm Cd) according to 45 Federal Register No. 231 (1980).

South African law makes no provision for cadmium removal from effluents to be discharged as specified in the South African Government Gazette (1962).

According to PRODUCTS FINISHING (1983), the 1984 requirement for electroplating effluents is 1.2 mg/l Cd as a daily maximum. This is clearly markedly less strict that proposed for mining and metallurgical effluents under RCRA.

PROCESSES FOR REMOVAL OF CADMIUM

Cadmium removal from effluents is achieved in much the same way as other base metals such as copper, lead, zinc, nickel, etc., i.e. by precipitation processes. Since cadmium is most unlikely to occur on its own in mining and mineral processing effluents, it will usually be removed in the same process as other related metals and end up in the same sludge.

There are two aspects of cadmium removal to be borne in mind. First, the levels likely to be required in dischargable effluents are much lower than for the other metals. For cadmium, levels of around 1-2 ppb and even into the parts per trillion range are talked about as being required to avoid environmental damage. This requirement is controversial, and although hopefully the ultimate needs will prove to be more reasonable, nonetheless the lowest possible levels in this range are being called for at this time.

Secondly, when cadmium is precipitated as a hydroxide, the precipitate is fluffy and somewhat more difficult to settle than most metal hydroxides.

Theoretical solubilities of hydroxides and sulfides of selected metals as presented in the EPA Treatability Manual (1982) are shown below. According to this table, cadmium is the least soluble of the metal hydroxides. As opposed to lead and zinc, the hydroxide is less soluble than the carbonate as well. Cadmium sulfide is very much less soluble than the hydroxide at 6×10^{-10}.

The wellknown curve of metal concentration versus pH shows that cadmium only starts to precipitate above pH 8 reaching a level of less than 0.1 ppm Cd only around pH 10.8 and above. To achieve minimum cadmium levels, the pH must increase to a level at which zinc will have started to increase again.

According to the EPA Treatability Manual which reviews contaminant removal from non-mining effluents, cadmium can be reduced by lime precipitation followed by settling to 0.05-0.10 ppm, and to 0.01-0.10 by sulfide precipitation followed by filtration. The EPA Treatability Manual (1982) also states that organic ligands of biological origin may affect the solubility and adsorption of cadmium.

Data shown in the EPA Treatability Manual (1982) refers to the SORG, et al. (1977) report that cadmium can be much more effectively removed by adding ferric sulfate as a coagulant achieving almost total removal from an 0.3 ppm solution at pH 9.0.

Cadmium forms complexes with numerous ligands, and the formation constants for these complexes is shown below as extracted from FULKERSON and GOELLER (1973).

Although the hydroxide solubility shows a cadmium concentration decreasing with pH up to pH 11.5 or so, the following graph from FULKERSON and GOELLER (1973) shows that if carbonate ions are present, then cadmium has a minimum solubility at pH 9.5 of 10^{-3} mg/l.

The presence of complexing agents clearly will have a marked effect on the degree to which cadmium can be removed by straightforward hydroxide precipitation. Ammonia, if present as in the effluent from ST JOE's zinc refinary at Monaca, will inhibit the precipitation of cadmium.

Cadmium sulfide, on the other hand, has such a low solubility at 10^{-10} that undoubtably this precipitate would be more stable than cyanide complexes, and precipitation to lower levels would be achievable.

PATTERSON (1975) also mentions that cadmium removal methods in use in industry are typically hydroxide or sulfide precipitation and ion exchange. He points out that cadmium is valuable enough that where waste streams are concentrated enough, electrolysis and evaporation may be viable. PATTERSON shows the results of cadmium removal by various processes which were able to reduce Cd down to 1.0 ppm to 0.70 ppb. Sulfide precipitation in the one reported case dropped Cd to 0.008 mg/l from an effluent containing 440-1000 ppm. Most interesting is the reported removal of Cd to 0.0007 ppm by hydroxide precipitation at pH 11 by CULP and CULP (1974) which is remarkable. the CULPS are principals in one of the most highly respected water treatment consulting engineering firms in the U.S.A. It was pointed out that changing the pH from 8 to 11 makes all the difference in cadmium precipitation, dropping the Cd in solution from 1 ppm to 0.00075 ppm. (This may have been a misprint, however.)

CULP and CULP (1974) also point out that co-precipitation with alum also effectively reduces the residual Cd, Zn, and Ni in solution when hydroxide precipitation is used.

MARUYAMA, et al. (1972) reported that cadmium is reasonably effectively co-precipitated with iron at pH 6. Results were obtained as follows:

Precipitation of metal salts versus pH

TABLE 3.1.3-1. THEORETICAL SOLUBILITIES OF HYDROXIDES AND SULFIDES OF SELECTED METALS IN PURE WATER [3-12]

Metal	Solubility of metal ion, mg/L: As hydroxide	As carbonate	As sulfide

Table III-4. Stepwise Formation Constants of Various Cadmium Complexes[a]

Ligand L	$\frac{[CdL]}{[Cd^{2+}][L]}$	$\frac{[CdL_2]}{[CdL][L]}$	$\frac{[CdL_3]}{[CdL_2][L]}$	$\frac{[CdL_4]}{[CdL_3][L]}$
Cyanide, CN^-	300,000	140,000	36,000	4000
Pyrophosphate, $P_2O_7^{4-}$	10,000	200		
Hydroxide, OH^-	8,500	(1000)	(180)	22
Ammonia, NH_3	550	150	30	10
Sulfate, SO_4^{2-}	130			
Iodide, I^-	120	5.9	140	30
Nitrite, NO_2^-	63	16	6	
Bromide, Br^-	57	4	10	2
Chloride, Cl^-	35	5	1	
Fluoride, F^-	3			

[a]All values are from Ref. 9 and, except for the case of sulfate, were determined in 2 to 3 molar salt solutions. The sulfate value refers to very dilute solutions, and as a result is somewhat higher than it otherwise would be. Electric charges are omitted in the formulae shown for the complexes.

Of the ligands shown above, the most important are cyanide (CN^-), hydroxide (OH^-), ammonia (NH_3), and chloride (Cl^-). Cyanide, ammonia and hydroxide complexes are relatively stable and form in a number of industrial or natural aqueous systems. Chloride complexes, while relatively much less stable, are important because chloride concentrations can be high in many aqueous systems. The distribution of the various complexes of Cd^{2+} formed by these ligands is shown as a function of the free ligand concentration in Fig. III-4.

The hydroxyl complexes are especially important because OH^- ion is always present in water, and its concentration can vary over a wide range as a result of the water dissociation equilibrium

$$H_2O \rightleftarrows H^+ + OH^-$$

$$K_w = [H^+][OH^-] = 10^{-14} \text{ moles}^2/\text{liter}^2 .$$

Hydroxyl complexes are formed by most metal cations in the periodic table. However, in many cases their identity and stability have been difficult to establish for two reasons: (1) the extent of their formation in solution is usually limited by the precipitation of the metal hydroxide, and (2) in addition to complexes containing only one metal ion, of the sort considered thus far, polymeric species, $M_x(OH)_y$, are often formed, the presence of which greatly complicates the interpretation of the experimental measurements.

Fig. III-6. The Solubility of Cadmium vs pH and vs Total Carbonate Concentration. For zero carbonate, the solid is cadmium hydroxide [$Cd(OH)_2$]. For the other curves it is cadmium carbonate ($CdCO_3$).

Precipitation Chemical Addition	Effluent*
45 mg/l Fe as $FeSO_4$ at pH 6	0.05 mg/l Cd
20 mg/l Fe as $FeSO_4$ plus 260 mg/l lime, pH 10.0	0.044 mg/l Cd
0 mg/l Fe plus 600 mg/l lime, pH 11.5	0.014 mg/l Cd

* After flocculation, settling, mixed media separation, and activated carbon columns.

It was reported in ENVIRON SCI. TECHNOLOGY (1971) that DuPont's patented Kastone process for oxidation-precipitation of metals from cyanide solution by peroxide addition precipitates cadmium as oxide while decomposing cyanide. It was claimed that the Cd oxide precipitate is easier to remove than cadmium hydroxide.

PATTERSON (1975) refers to two applications of sulfide precipitation of cadmium including one in acid mine drainage (LARSEN, et al., 1973).

SHIMOIIZAKA (1972) describes one method of removing cadmium using xanthate and describes a method to recover xanthate from cadmium xanthate.

The PERMUTIT COMPANY in their promotional literature describes the Sulfex process which employs freshly prepared iron sulfide in a sludge blanket contactor. More information on this patented process is available from:

PERMUTIT COMPANY,INC.
Post Office Box 355
Paramus, NJ 07652
(201) 564-6000
Telex: 134-488
Robert V. Nagiel
Product Manager

The PERMUTIT COMPANY was contacted, and it appears that their experience in the application of the Sulfex process is limited to relatively small streams such as plating wastes. PERMUTIT has developed a sludge blanket clarifier device to optimize the Sulfex process and avoid the possibility of excess sulfide ion concentrations in solution.

SHIMOIIZAKA and MATSUOKA (1975) reviewed the precipitation of cadmium and arsenic with $CaCO_3$ and $Ca(OH)_3$. The effects of coexisting ferrous/ferric ions on the precipitation of Cd^{2+}, AsO_3^{3-}, and $As_2O_3^{3-}$ and the oxidation of ferrous ions with air, bacteria, and oxidants in the presence of a catalyst were reviewed.

INCO METALS, INC., according to Butler (1984, personal communication) on applying lime precipitation and settling, achieves an effluent from their Copper Cliff water treatment plant at Sudbury of less than 0.002 ppm Cd which is remarkable for a process that does not employ filtration or one of the more exotic precipitation chemistries. Confirmation and more information could be requested from:

STARCH XANTHATE REMOVAL OF Cd

WING, et al. (1974) showed that starch xanthate could remove Cd from a 56.2 mg/l solution at pH 3.1 down to 0.008 mg/l as compared with precipitation by addition of

hydroxides to 29,600 and 4,500 ppb at pH 7 and 9 respectively. WING, et al. (1974) showed that at the optimum pH of 6.7, the Ksp for metal ethyl xanthate was 2.6×10^{-14}.

Later in their paper, WING, et al. (1974) showed that cadmium in a solution containing 10 ppb Cd could be reduced to 2 ppb using starch xanthate PVBTMAC. A second solution was dropped from 29 ppb to 11 ppb. PVBTMAC is added at 1 ml to 50 ml of sample solution and starch xanthate with 0.23 degree of substitution to obtain maximum flocculation. PVBTMAC (poly-vinyl benzyltrimethyl ammonium chloride) is a cationic co-precipitant. Robert Wing is employed at:

CEREAL PRODUCTS LABORATORY
Northern Regional Reseach Lab
Agricultural Research Service
U.S. Dept. of Agriculture
Peoria, Illinois

WING, et al. (1974) describe the principles of using starch xanthate for effluent treatment in which the SH^- and $S^=$ groups are attached to insoluble starch molecules. They indicate that this method of heavy metal ion removal for polishing has several advantages:

- Recovery of the adsorbant is simple. Treating the polyelectrolyte complex with mild acid releases the metal and regenerates the starch xanthate.
- The volume of sludge is small compared with that from lime treatment.
- The physical nature of the sludge is not gelatinous as is usual with basic precipitation, and the floc settles faster and can be removed more easily by filtration, centrifuging, or settling.
- In some effluents, suspended solids have to be removed before treatment; this is not necessary with the xanthate method.
- Careful control of pH is necessary when heavy metals are precipitated with a base because some metallic hydroxides will redissolve if the pH is too high. The starch xanthate method is claimed to be effective over the pH range 3 to 11.
- Several chemical treatments require a large excess of reagent to get the heavy metal levels down. In the xanthate method, only a slight excess of reagent is necessary.
- A single treatment will remove most metals to very low levels equivalent to sulfide precipitation.

The cationic polymer PVBTMAC is, or was, available from DOW CHEMICAL COMPANY, Midland, Michigan, as Product No. Experimental Resin ZX-2611.F. Insoluble starch xanthate is also produced and marketed by:

POLLUTION TECHNOLOGY SYSTEMS, INC.
3015 Benton Street
Garland, TX 75042
(214) 272-4010
Mile Coward
Manager-Systems Engineering

POLLUTION TECHNOLOGY SYSTEMS' insoluble starch xanthate ISX/5-CM is applied at a ratio 12.0:1 ISX to Cd by weight.

No data on any particular applications of this product was obtained, nor on the cost of the material or process.

CHELATION RECOVERY

POLLUTION TECHNOLOGY SYSTEMS, INC. offers a product known as DX-2000 which is a buffered organic material that effectively precipitates complexed or chelated cationic heavy metals of 10 mg/l or greater from difficult-to-treat industrial process waters effective over a pH range of 3-11. 155 grams of Cd^{+2} can be removed per liter DX-2000. No case histories were available on its use, however. More information is available from POLLUTION TECHNOLOGY SYSTEMS, INC., Garland, Texas; contact: Mike Coward.

Another company that has devoted an enormous effort to removal of low levels of metals from solution is DEVOE-HOLBEIN, INC. A paper by HOLBEIN, et al. (____) was included in Chapter 25 on Removal of Contaminants, and more information is available from:

DEVOE-HOLBEIN (CANADA), INC.
175 Bouchard Blvd.
Dorval, Quebec H95 1A9
Canada
(514) 636-6042
Dr. Bruce E. Holbein
Dr. L. G. Neirink

One DEVOE-HOLBEIN formulation, DH-516, was able to remove Cd from an inflow concentration of less than 1 ppb which is a truly remarkable achievement even though the nature of the test or the test solution was not described.

Although the cost of the formulation in laboratory scale quantities is very high, the developers envisage that should a large market develop, the cost of mass-produced material would be reasonable--how reasonable is anybody's guess. Some of the compositions are extremely selective, too. Another demonstrated advantage is the ability

to regenerate the composition in may cases quantitatively in only one bed volume of 2NHCl.

In a full scale test using a 140 l-composition column operating on influent with 2500 ppm Cd effluent ran 0.01 ppm. About 80% of the composition-bound Cd would be displaced in 0.15-bed volumes of regenerant and 100% in two-bed volumes.

Although little is as yet known about the economics and applicability of the DEVOE-HOLBEIN processes and compositions, this frontier technology quite clearly has some very special aspects and is of considerable importance in future metals removal.

MAGNESIUM OXIDE PRECIPITATION

BLACK, et al. (1974) describe the tests of a process in which about 40 mg/l of magnesium precipitated as a carbonate in water containing 0.36 ppm Cd could be reduced by 99% to 0.01 ppm Cd in solution. On filtration, the cadmium concentration was dropped to 0.005 ppm or less.

The tests were carried out at the Montgomery Water and Sanitary Sewer Board, Post Office Box 1631, Montgomery, Alabama, and the report is available from NTIS as PB-241 884, EPA-660/2-75-006. Magnesium carbonate and CO_2 are recycled.

The development and demonstration of the recyclable magnesium carbonate water treatment process was carried out by:

BLACK, CROW AND EIDSNESS, INC.
777 South Lawrence Street
Mongomery, Alabama
A. P. Black
C. G. Thompson

This process has been employed on a commercial scale at Montgomery, Alabama, and in Ohio for municipal water treatment, but none has been found on mining or mineral processing effluents.

ION EXCHANGE

Ion exchange resins are available that are metal specific, but such processes and systems for large flows are invariably expensive and require a fair degree of expertise to operate and maintain.

In the case of Cd, except where there is enough Cd for profitable recovery as a product, selective removal of Cd is unlikely to be needed; more likely, removal of all toxic metals

CADMIUM STUDY

The effectiveness of this new process in the removal of heavy metals was studied in both jar tests and in the pilot plant. Cadmium was chosen because of its easy and accurate determination by atomic adsorption as well as for the fact that it would likely be solubilized at a pH of 7.0, the pH of sludge carbonation. The results of jar tests are shown in Tables 12, 13 and 14.

TABLE 12. EFFECTIVENESS OF ALUM IN REMOVING CADMIUM

42.2	.01	99

Reagent grade cadmium chloride was used as a source of cadmium in all studies. Samples taken after settling were filtered through Whatman #40 paper prior to analysis. Unfiltered samples taken during the study reported in Table 15 showed similar removals.

During pilot plant studies cadmium chloride was added continously to the raw water for a period of ten days. The magnesium and lime dosage was 40 and 100 mg/l respectively. The raw water cadmium level ranged from 0.75 to 1.0 mg/l. The settled water ranged from 0.003 to 0.007 mg/l and the filtered water ranged from 0.000 to 0.005 mg/l of cadmium. Table 14 summarizes the analytical results.

Cadmium was not released in any appreciable amounts on carbonation regardless of the pH to which carbonation was carried. A pH range of 6.0 to 7.7 generally resulted in a cadmium concentration of 0.1 mg/l or less in the recycled magnesium bicarbonate solution.

FILTRATION STUDIES

Two identical 1.5 square foot pilot filters with continuous turbidity monitoring equipment were made available to the project by the Taulman Company, Atlanta, Georgia. Combinations of sand and various sized anthracite media were evaluated as to water quality produced and operating characteristics. Initial studies compared the filterability of the alum treated water, piped from the full scale plant, with the stabilized magnesium treated water. Later studies were made using the proper stabilization pH, type media, and depths of sand anthracite required.

These studies allowed the following conclusions:

1) Filtration efficiency is directly related to

TABLE 15. PILOT PLANT RESULTS - CADMIUM STUDY
(Cadmium concentration - ppm mg/l)

Date/ Time	Raw Water	Carbonate Sludge	Clarified Water	Filtered Water

7/28	--	0.05	--	--

coagulation and clarification efficiency for both the alum and magnesium process. When proper pretreatment has not been accomplished, filtration will not provide adequate treatment.

2) The carryover of calcium carbonate will not shorten filter runs or reduce the quality of the filtered water.

3) In Montgomery, filtration of waters which had not been stabilized below pH 9.0 resulted in calcium carbonate precipitation on the anthracite and sand media. Precipitation occurred more rapidly and extensively on the sand. Extremely short filter runs were obtained under these conditions and the calcium carbonate formed could not be washed from the filter. These "balls" gradually worked their way into the gravel underdrain, eventually requiring acidification treatment of the filter. These studies provided a severe warning as to the necessity of adequately maintaining the proper stabilization pH in full scale operation.

4) Maximum filter runs were obtained with four inches of 1.2 mm anthracite media over twenty-four inches of standard filter sand. Increase in anthracite media depth did not increase filter performance either in length of filter run or water quality produced.

5) In general, two filter rates were studied, 2 and 3.5 gal./sq.ft./min. The higher rate on the average produced a slightly better water quality. It appeared that backwash requirements were essentially the same, based on percentage of the water produced during the run.

6) The geometry of the pilot filters was such that backwashing was not equivalent to the full scale filters. Side wall friction was considerably higher, resulting in an unusual backwash pattern. Considerable care was required to prevent backwashing of media from the system. Backwash rates of 15 gal./sq.ft./min were not possible, so that some of the calcium found on the media could possibly have been removed at higher backwash rates.

7) Finished water stabilization appears to enhance filtration efficiency. Clarifier turbidity carryover serves as a nucleus for calcium carbonate precipitation, enlarging the particle size and changing the chemical-physical properties, increasing the opportunity for removal by filtration.

8) Calcium carbonate carryover to the filters does not shorten filter runs and can be easily removed on backwash. Calcium carbonate precipitation on the filter media drastically shortens filter runs and cannot be removed efficiently by backwashing.

MONTGOMERY FULL SCALE STUDIES

From November 1972 until June 1973 full scale evaluation of the Magnesium Process was conducted in Montgomery. The Magnesium Process was found to compare favorably with the alum process in both overall operation and water quality produced.

During the study voluminous data were collected at many points of the process. Figure 16 illustrates a summary of process control points and a brief discussion as to

at a low cost is needed and if possible, without the need to change the pH of the water being treated more than necessary.

NATURAL BIOLOGICAL SYSTEMS

WIXSON describes a successful biological system in a meander arrangement built into an effluent stream at AMAX-HOMESTAKE's Buick Mine-Mill in the New Lead Belt of Missouri. Heavy metals are very effectively removed from the effluent in this polishing step as well as organic flotation reagents. In this case, algae grow prolifically in the meandor system. More details are provided in Chapter 25.

ST. JOE MINERALS at Edwards, New York, also finds that an effluent decanted from their Edwards tailing pond is polished on passing through a natural marsh area to below 1 ppb Cd as discussed in chapters 24 and 25.

Individuals with a particular interest and achievement in this field include:

J. G. Reilly

Randol International Ltd. believes that passive, natural biological polishing eco-systems, as well as the field of bacterial metal removal systems, are important avenues for future development work.

When sulfite is present in water, sulfide consumption can be excessive at low pH before metals will precipitate. This may be one way that natural biological polishing can be inhibited, i.e., if the effluent contains thiosulfates or sulfite and where biological reduction of sulfate to sulfide is part of the polishing process. However, it appears that very low Cd levels can be achieved through effective removal of very small hydroxide particles by filtration, which would occur in a marsh with dense vegetation.

AMAX MOLYBDENUM DIVISION, MOUNT EMMONS, COLORADO

AMAX stabilized the site of the old Keystone Zinc Mine and mill outside Crested Butte, Colorado. This entailed a $1.9 million program to stabilize and recontour old tailings dams and a further $10.9 million for a state of the art (1981) water treatment plant with a

capacity of 2,000 U.S. gpm to treat collected seepage and acid mine drainage containing, Fe, Zn, Mn, Ca, Cd, and Pb.

The plant is located at 11,000 feet, and one of the parameters is low water temperature, close to 0°C for many months of the year, which makes coagulation of precipitates more difficult.

The plant employs electrocoagulation and Swift (now Dravo) Lectroclear flotation for recovery of the precipitate followed by filtration of the effluent and beltpress dewatering of the precipitate sludge to 12% solids and cement stabilization as described in Appendix I.

Cadmium levels are reduced from 0.42-0.70 ppm to 0.001 ppm in the polished effluent. This clearly demonstrates the effectiveness of sand-filtration in reducing suspended Cd hydroxide as a polishing step.

Based on pilot scale tests by AMAX, dissolved air flotation was found to work as well as Lectroclear flotation and would be less costly to install and operate for a new installation.

There are undoubtably less costly ways of treating AMD in flows comparable to Mt. Emmons. Lectroclear flotation was selected here before AMD treatment processes had all been tested and at the time, this process was the only one that had been demonstrated in comparable conditions when a decision had to be made.

ARGO TUNNEL ACID MINE DRAINAGE

Acid mine drainage from the Argo Tunnel, Idaho Springs, Colorado, contains iron, copper, lead, maganese, nickel, zinc, and cadmium in excess of proposed water quality standards. Cadmium levels range between 0.23-0.29 ppm, and the proposed water standard is shown by HOLM and SIMPSON (1981) as 0.002 ppm.

HOLM and SIMPSON (1981) whose paper is included in the chapter on Acid Mine Drainage Treatment, describe a test installation of the Wannamaker continuous concentrator which incorporates the principles of sludge recycling, NaOH precipitation, and crossflow filtration to yield a dense slurry.

When adjusted to pH 9.2, cadmium was dropped to .04 mg/l from feed at 0.29 mg/l. This does not meet the proposed water standard of 0.002 ppm but is very low nonetheless. Most other metals were reduced to below the proposed water quality standard.

The Wannamaker Continuous Concentrator has not been used on a commercial scale, but since a unit capable of treating 80 gpm would cost around $5,000, it would appear that

for $100,000, a system capable of treating 1,600 gpm could be installed. The units are, however, not commercially available although other larger capacity cross-flow micro filtration units are available from other suppliers.

More information on the ARGO tunnel test is available in HOLM and SIMPSON (1981) and from:

W. W. (BILL) WANNAMAKER
Post Office Box 1121
Camden, SC 29020
(800) 845-2202

Information on a commercial scale crossflow filtration device that could possibly be used in the place of the Wannamaker Continuous Concentrator could be designed around a system offered by:

NEPTUNE MICROFLOC
Post Office Box 612
1965 Airport Road
Corvallis, OR 97339
(503) 754-7654

In order to reduce the Cd level further to below 0.002 ppm, RANDOL INTERNATIONAL LTD. proposes that the following be tested:

1. Add freshly prepared FeS to the recirculating slurry in the cross flow filtration unit with pH adjustment as before.

2. Set up the cross flow filtration system in a sludge recycle HDS mode with lime addition as opposed to NaOH and some FeS for polishing. This would require an additional tank for sludge/lime premixing.

No known tests of the above have ever been carried out.

BOLIDEN AB, SKELLEFTHAM

Boliden AB, at its copper smelter and metallurgical complex, Skellefteå, applies sulfide precipitation at several points in the plant for metal removal. One effluent treated has the following composition:

These metals are effectively removed by adding Na_2S. Because arsenic sulfide As_2S_3 is insoluble only at low pH, around 3, they have to use a six-step process.

1. Precipitaton of As_2S_3 and other metals, pH 3.9.
2. Anionic polymer addition.
3. Sedimentation.
4. Multimedia filtration at pH 3.8.
5. Lime addition to pH 11.5.
6. CaF_2 sedimentation and decant.

Typical residual metal concentrations obtained by full-scale test run (Boliden Metall).

Because of the presence of arsenic and the need to operate at a low pH, sulfide reacts with SO_2 or $SO_3^{=}$ present in solution. This consumes excess $S^{=}$ which is expensive. (At higher pH, the reaction is minimal so operating at high pH 6-8 is preferable when arsenic is not present.)

At BOLIDEN, solutions contain $SO_3^{=}$, so considerable amounts of S^{o} and $S_2O_3^{=}$ are generated. Sulfur is collected with the metal sulfide precipitates. According to BLYTHE, et al. (1981), treated solutions with 0.02-0.06 ppm Cd are achieved.

BOLIDEN was stockpiling the recovered sulfide sludges with a view to possible future metal value recovery by hydrometallurgy.

According to BHATTACHARYYA (1985, personal communication), the generation of H_2S that could be expected has not been a problem at this plant.

More information can be obtained in the more detailed EPA Report PB81-209-272 by SCHWITZGEBEL, et al. (1981) and from:

BOLIDEN METALL AB
Skellefteham,
Sweden
Rolf Sevedberg

BOLIDEN built a commercial scale plant to treat 800,000 gpd 3600 m^3/d process effluent and collected runoff. Runoff contains arsenic in this case. From a metals removal point of view, the process works well. BOLIDEN uses a pH meter to control sulfide addition. There is an abrupt pH change as soon as $S^=$ is in excess.

LEAD SMELTER B, EASTERN CANADA

Cadmium contamination of seawater in a harbour on the Atlantic seaboard was recognized as a result of earlier discharges from a lead smelter and refinery in Canada, as described by BEWERS, et al. (1984) and DUGDALE and HUMMEL (1977), which manifested itself in lobsters with elevated Cd content.

This contamination was greatly reduced by segregating effluents which contain Cd from those that do not and by diverting unaffected runoff waters from the plantsite. Recycling of slag granulation water reduced the volume of water affected, and dry disposal of slag at a remote site prevented leachate from the slag from reaching the ocean. At 140 m^3/h (design), the effluent treatment plant was installed employing lime neutralization and settling to treat all effluents before discharge to the ocean as described in Appendix I.

The Cd and As levels in recycled water have risen steadily since the program was instituted, and the effluent treatment plant discharge runs between 0.06-40 ppm Cd which sometimes exceeds the 0.5 ppm design, mainly due to underdesign of the clarifier and lack of a polishing filter shown to be essential above in achieving the very low levels required.

Sludges containing 2-3% Cd, up to 13% As, 5-10% Zn, and 1% pb at 1-5% solids are recycled to the sinter plant in the hope that these metals will ultimately end up in a stabilized form in the lead smelter slag or in a Cd fluedust which is sold to a cadmium producer. It is possible that generating a high density sludge, which could be removed from the system and stabilized for disposal or would have a much higher Cd content for shipment, might possibly be considered for similar applications.

Design capital and operating cost for the water management and treatment program instituted in 1980/81 was C$427,000 and C$245/day respectively.

However, the above information was obtained from reliable sources and is an important illustration of what is required to achieve low Cd levels as well as results when no polishing filter is installed. The identity of the operation is, after all, of secondary importance. Please bear in mind that this report is submitted to you on a confidential basis.

Cu-Pb-Zn Mine-Mill B

A large mine-mill-concentrator complex shown in Appendix I as Mine-Mill B is located in eastern Canada. Treated minewater and tailings decant in excess of that which can be recycled to the process are discharged to streams that are part of an important salmon fishery.

Cd levels in the AMD and tailings decant are not very high at 0.21-2.30 ppm Cd and drop to around 0.04-0.06 ppm in the final effluent which, after dilution, results in a Cd level of 0.01-0.03 mg/l Cd in the riverwater.

The operation uses straightforward lime neutralization for treatment of their minewater and tailings pond decant solutions. Lime adjusted effluents were previously clarified in a lamella thickener which had to be abandoned in 1984 due to severe scaling problems. Settling in an aging pond has been applied. However, until the wall of the aging pond could be raised to provide the additional capacity needed, decanted effluent overflowing from this pond ran 0.23 ppm Cd which is in excess of effluent limit of 0.05 ppm Cd.

It is believed that this operation has simpliflied its flotation circuit arrangement which reputedly will allow the use of close to 100% water recycle, which will allow them to reduce the volume of effluent to be discharged. However, at the time of the visit, this was still in the development stages and premature for discussion. Of interest in the Appendix I report is the high cost of effluent treatment at this operation where lime precipitation and settling costs between C$0.60-C$1.83/m^3.

COTTER CORPORATION - SCHWARZWALDER MINE

This uranium mine is located in the front range of the Rockies at Golden, Colorado, some 125 miles away from the mill that processes the ore. Mine drainage, although neutral pH, contains uranium and radium which must be removed from solution before the excess water can be discarded to a stream. It also contains 0.002 mg/l Cd. In the unique continuous fixed bed ion exchange system employed to remove uranium and described by PALMER, et al. (1984), cadmium levels are reduced from 0.002 to 0.0004 mg/l indicating an effective cadmium polishing step--albeit from an already very low level but still not quite achieving the EPA criteria considered safe for aqueous organisms. In this case, the eluate contains concentrated uranium values which are shipped to the mill for precipitation. The minute quantities of cadmium in the eluate ultimately ends up in the Cotter Mill process water sand tailings.

EXXON MINERALS COMPANY, CRANDON, WISCONSIN, PROJECT

EXXON is evaluating and designing a mine-mill-tailings system for a complex sulfide orebody at Crandon, Wisconsin.

Because the deposit is located in an area with net precipitaton, zero discharge will not be possible. Some effluent will have to be discharged.

EXXON has undertaken a massive and detailed study of all possible ways of treating the effluent to meet regulatory requirements. Since the state of Wisconsin was initially not very experienced in dealing with mine and mill development, a clearcut regulation on mine-mill effluents did not exist, and the company had first to help the state formulate their mining waste control policy.

Many of the developments are sub-judice, so not too much detail is available although, undoubtably, a copy of the Environmental Impact Statement will eventually be available in Madison, Wisconsin.

It is rumored that initially the state of Wisconsin specified 0.2 ppb Cd as the maximum level for Cd in effluents. Subsequently this is believed to have been "relaxed" to 1 ppb. As of January, 1985, the effluent discharge limits for the Crandon project have still not been established by the state.

EXXON has examined just about every possible method of removing heavy metals from their proposed effluent including lime precipitaton, sulfide precipitation, and starch xanthate precipitation. In due course, details of this work will hopefully be published.

Much of the water management and water treatment investigation was carried out by Dr. John Shafer who has now been transferred to a different division of EXXON in Houston. The following people would be able to direct inquiries:

RAND MINES ERPM, WITWATERSRAND, SOUTH AFRICA

A demonstration pilot plant to reduce TDS, particularly $SO_4^=$, from neutralized acid mine drainage pumped from underground at the Hercules Shaft, EAST RAND PROPRIETORY MINES LTD. as described in the Appendix I trip report, was installed in 1984 with about 5 m^3/d capacity.

The process employs seeded slurry recycling and achieves 95% plus water recovery from a feedwater which is nearly saturated with gypsum.

The process is operated at a controlled slightly acidic pH; in other words, with acid addition to maintain the pH in the operating range for the tubular cellulose acetate membrane R.O. modules.

Interestingly enough, the cadmium level is reduced from 0.02 ppm to 0.005 ppm. The Cd level is very low to start with, and it would be interesting to determine what the removal efficiency would be like using this process on a solution with higher cadmium levels.

At 0.005 ppm in the effluent, Cd is removed by the R.O. membrane to a level much lower than its solubility at the same pH which would be in the tens of mg/l.

Cadmium removal was not one of the objectives of this seeded slurry R.O. demonstration plant, yet the results show that R.O. may conceivably be used to effectively reduce Cd levels at a low pH.

Operating costs of tubular R.O. membrane units are currently estimated at around Rands 0.50/m^3 (U.S. \$0.22/m^3 or about U.S. \$1.00/1,000 U.S. gallons).

CHAPTER 35

CALCIUM Ca AND MAGNESIUM Mg

Calcium and magnesium are common constituents of water of virtually all kinds from seawater to wellwater and including most mine and mill effluents. Ca and Mg are not toxic, and no water quality criteria or regulatory limits were encountered for calcium and magnesium for mine and mill effluents.

Calcium and magnesium enter the water supply in many different ways. In nature, acidic water in contact with soil and rocks containing calcium carbonate (limestone, marble, and calcite) will dissolve calcium, and magnesium is dissolved from dolomite. Dissolved CO_2 from the air can drop the pH enough that calcium goes into solution. The more recently recognized phenomenon of acid rain also dissolves Ca and Mg from natural soils and rocks. Dissolution of calcium into groundwater is discussed by HEM (1970).

Lime is, of course, very commonly used to adjust pH of solutions as well as municipal drinking water. It is used in very large quantities to neutralize acid mine drainage and all kinds of gas scrubbing effluents, particularly from coal-burning power plants.

Gypsum, $CaSO_4$, has a solubility of around 2000 mg/l and consequently, as long as it is present below this level, all the $CaSO_4$ will be in solution. $CaSO_4$ waters readily supersaturate, however.

Calcium carbonate at neutral and high pH is much less soluble than calcium sulfate. A curve showing the solubility of calcium as $CaCO_3$ versus carbonate content in mg/l $CaCO_3$ is shown below indicating the steep decrease in calcium solubility in water as $CO_3^{=}$ is added.

Acidity-alkalinity relationships in water in relation to the solubility of minerals such as calcium carbonate and magnesium hydroxide is more complicated to predict than the solubility product suggests. Even for the simplest case of calcium precipitating from water as calcium carbonate, numerous interrelated equilibrium reactions occur at the same time and affect the interpretation of simple chemical data. For that reason, the NALCO Water Handbook states that water chemists usually rely on data based on empirical data.

Figure 4.7 shows data generally used for predicting calcium carbonate solubility which is useful in precipitation of calcium used in the lime-softening operation. The difference in results between the hot process at around 100°C and the cold process is considerably beyond what would be predicted on purely solubility data which show a decrease of only about 2 mg/l solubility at the higher temperature. The empirical temperature effect is believed to be caused by factors such as rate of reaction (which halves for each 10°C

temperature drop), the nature of the crystalline or amorphous precipitate, and the possible effect of coagulating organic materials at higher temperatures.

Another example of organic coagulant effects is in cold lime-softening of municipal sewage in which the residual calcium carbonate level is invariably higher than when the same process is used in the treatment of fresh water as shown in figure 4-8 from the Nalco Water Handbook. If, however, the sewage is heated above approximately 160°F (71°C), then results approach those achieved in cold water

It has also been found that if magnesium is present in solution, then the residual calcium in solution may be increased. Other impurities such as strontium have the same effect of increasing the solubility of $CaCO_3$. There is no substitute for an actual bench test to determine the response of a given water to lime treatment.

When water is softened with lime in the pH range 9.5-10.5, magnesium precipitates as the hydroxide, and the precipitate is positively charged. In the same pH range, $CaCO_3$ precipitate is negatively charged. Silica in the system is usually present as a strong negatively charged colloid, or may be present as sodium aluminate which is a strong anionic complex. All of this accounts for the co-precipitation of magnesium with calcium and the strong adsorption of silica on $Mg(OH)_2$, as well as the low residual magnesium often achieved by the treatment of water with sodium aluminate as well as lime.

In conventional softening operations, it is usual to show that lime treatment of fresh water produces a $CaCO_3$ solubility of about 35 mg/l cold and 35 mg/l hot and a residual magnesium hydroxide solubility of around 35 mg/l cold and 2-3 mg/l hot.

Figure 4.7 $CaCO_3$ solubility in hot and cold systems—empirical data based on 60–90 minutes reaction time and settling time.

Figure 4.8 Cold lime softening of sewage (upper two curves) compared to noncontaminated water.

Source: NALCO (1979)

CALCIUM AND MAGNESIUM

Calcium carbonate and magnesium hydroxide are precipitated in the lime softening operation. However, these can also precipitate from unstable water--that is, water containing these materials in a supersaturated condition--if anything else is done to the system to upset the equilibrium. This can be an increase in temperature, a decrease in pressure, turbulence, or contact with surfaces which seed the chemical precipitation. The most common product of instability of fresh water is $CaCO_3$; in seawater, the usual precipitate is $Mg(OH)_2$ or one of its complex carbonate hydroxide salts.

Consequently, although it is not likely that calcium will need to be removed from water to meet effluent discharge limitations, calcium and magnesium do play a critical role in scale formation when reclaimed waters are recycled to a metallurgical process. In acidic systems, the formation of gypsum scale is particularly a problem.

In mineral processing operations, these phenomena may, on occasion, completely rule out the use of lamella plate pack clarification, for example. Elsewhere, high calcium levels could lead to severe fouling in the pores of in-situ leach wellfields or in the ion exchange metal recovery units treating the solution. Special provisions may be required in deep-bed sand filtration.

In acid mine drainage desalination to remove high TDS as is being tested in South Africa, desalination of water containing nearly saturated gypsum concentrations would be expected to cause membrane fouling problems as TDS levels increase in the concentrate. Sequestering agents can allow gypsum in the concentrate to increase up to three or four times saturation before gypsum crystallizes out to foul the system.

In heap leaching operations, calcium salts can precipitate out as $CaCO_3$ or $CaSO_4$ or as some Ca, Mg carbonate-hydroxy scale and cause problems with the heap porosity.

In flotation mills, lime is often used as a pH modifying reagent, and it can be introduced into minewater as a result of using cement in backfill. High Ca and Mg process waters are believed to interfere with the efficiency of some flotation recoveries or their selectivity. However, they may also be an indication of plant feed contamination by cement containing dispersants.

When treating gold ores by the carbon in pulp process, it has been found that magnesium species in the pulp have a positive zeta potential. MENNE (1984, personal communication) advises that the presence or absence of magnesium in cyanided pulps fed to a CIP circuit has a marked impact on compatability of the pulp and the activated charcoal used. This effect can alter the performance ranking of carbons for gold recovery from such pulps depending on the presence or absence of magnesium which undoubtably will be in the hydroxide form in such pulps, usually at pH 9-10.5.

HOFFMAN (1984) reported on the Schullsberg Mine of EAGLE PICHER INDUSTRIES in Wisconsin where, when mining stopped and the water table was allowed to rise, sulfate ion concentrations increased dramatically as magnesium and calcium sulfate dissolved from dolomitic rocks as a result of acid mine drainage.

In this case, the calcium and sulfate ion concentrations exceeded the calcium sulfate solubility product by many times due to the presence of magnesium to the extent that at 3,500 ppm SO_4 levels, the groundwater became no longer suitable for human consumption or stock watering.

The relationship of calcium carbonate solubility and the bicarbonate-carbonate equilibrium shift with pH is of particular importance in metallurgical circuits, especially those in which process solutions and/or tailings reclaim solutions are recycled.

Because as pH is increased (most often through addition of lime, but also Na_2CO_3, or NaOH), the following equilibrium shifts to the right.

$$HCO_3^- + OH^- = CO_3^=$$

Consequently, solubility of calcium in solution or added in the pH adjustment step is greatly reduced as pH is increased and as the HCO_3^- concentration in the feedwater is increased. In the graph from HEM (1970) shown below, if bicarbonate is present at 100 ppm at pH 6.5, then 700 mg/l Ca can be in solution without being saturated. If, however, the pH is increased to 8 and 9, the solubility of Ca drops to 15 and 1.5 ppm respectively. Consequently, the effect of pH increases on $CaCO_3$ solubility is pronounced and has a big impact on scaling wherever waters are mined or pH adjusted such as in gold cyanidation circuits, for example, and flotation circuits, even if NaOH is used for pH adjustment, and particularly if Na_2CO_3 is used.

When using carbonate and hydroxide to precipitate calcium from solutions, it is found that calcium carbonate precipitates at pH 9-11.2. Above pH 11.8, calcium forms a soluble complex with hydroxide which competes with $CaCO_3$ precipitation, and the calcium concentration in solution is not as low as at pH 11.2.

$$\begin{aligned} Ca\,(HCO_3)_2 &= Ca^{2+} + 2HCO_3^- \\ 2HCO_3^- + 20H^- &= 2CO_3^= + 2H_20 \\ Ca^{2+} + CO_3^= &= \underline{CaCO_3} \\ \hline Ca(HCO_3)_2 + 20H^- &= \underline{CaCO_3} + 2H_20 + CO_3^= \end{aligned}$$

When lime water is used as the base:

$$Ca(HCO_3)_2 + Ca(OH)_2 = \underline{2CaCO_3} = 2H_20$$

At a high pH above pH 11.8:

$$CaCO_3 + 4OH^- = [Ca(OH)_4]^= + CO_3^=$$

SCALE IN CIP AND HEAP LEACHING

The effect of calcium sulfate and calcium carbonate scaling on carbon fouling on heap leaching and in CIP gold recovery plants is clearly important. CALGON CORP. and NALCO have both studied these phenomena, and major breakthroughs have been made in scale inhibition through addition of reagents. More information is available from:

RANDOL INTERNATIONAL LTD. believes that some simple water management practices can also help reduce the scaling problem with or without the use of additives.

One highly innovative way of controlling the sealing phenomenon was observed during a visit to PINSON MINING COMPANY, Nevada. It is believed that this simple innovation was suggested and first implemented by Roger Leonard, Plant Metallurgist at PINSON at that time. It was observed that scale formation and calcium carbonate precipitates form at the point where water from different sources are mixed, e.g., tailings dam return water mixed with fresh water. To overcome problems of scaling and carbon fouling, PINSON MINING adds fresh water to the circuit at the tailings pond and allows the solutions to equilibrate and precipitate to decant further in the dam before recycling solution to the plant. Taking this effect further, it would be possible to inject fresh water into the tailings line allowing the tailings solids in the slurry to nucleate precipitates and bring the water mixture to equilibrium before it is decanted and returned to the mill. In this way, most of the scale should precipitate in the tailings pond rather than in the plant or on the activated carbon.

To avoid $CaCO_3$ precipitation, it is possible to reduce calcium levels, carbonate levels, or both. It is also possible to equilibrate the solution at a higher pH, but not beyond pH 11.8, and then to adjust this slightly downwards so that the solubility of $CaCO_3$ is increased.

BETHLEHEM STEEL CORP. at their Panther Valley Mines in Pennsylvania, an anthacite coal producer, uses vigorous aeration at low pH to blow off CO_2. It is found that by doing this, the pH increases, and the amount of lime consumed is reduced more than enough to pay for the decarbonization, and the smaller amount of precipitate puts less load on the thickener. The economics of this step are not known in detail, but BETHLEHEM STEEL finds it cost effective at this location where lime costs are low.

[Ca] reduction is possible by lime or lime-soda softening processes. Eight examples of acid mine drainage neutralization by various processes show that in most cases where lime is added, [Ca] will be increased. In only two of these, where reverse osmosis and ion exchange are applied, were Ca values dropped.

Magnesium concentrations in AMD were reduced to relatively low levels, however, by ion exchange, reverse osmosis, alumina lime-soda treatment, and lime-soda treatment at

hardness less than 100 ppm. In the remaining processes, magnesium levels were only marginally reduced.

The lime softening and lime-soda softening processes are discussed in greater detail in The NALCO Water Handbook.

During this investigaton, very few mines and mills were found to be employing water softening Ca removal processes for use of the water as process water. Several do use softening as a precursor to ion exchange demineralization for boiler feedwater, however.

Calcium fouling of activated charcoal is a common phenomenon in gold recovery CIP operations. The use of air agitation which introduces CO_2 into the pulp solution undoubtably enhances the effect, especially when high concentrations of free cyanide are employed. It has been pointed out that $CaCO_3$ fouling of carbon can be reduced by operating at a lower pH or through the use of additives.

In some heap leaching operations in cold climates, the solutions are heated to extend the operating season. Submerged exhaust gas heaters were initially popular for this purpose; however, the CO_2 in these gases could be expected to precipitate calcium from the solutions which could cause problems on the heaps and in the carbon adsorption tanks.

A very interesting case where $CaCO_3$ solubility in solutions is manipulated was described by YAN (1983):

In in-situ leaching of uranium using a carbonate lixiviant, CO_2 may be added to the leach solution under pressure. When the pregnant solution is pumped back to the surface, uranium is recovered by ion exchange. Open ion exchange vessels are preferred to closed pressurized IX systems. When the pregnant solution reaches the surface at ambient pressure, excess CO_2 boils off. When this occurs, $\underline{CaCO_3}$ precipitates. While CO_2 is under high pressure, Ca is kept in solution as a bicarbonate complex. When the excess CO_2 boils off on lowering the pressure, $\underline{CaCO_3}$ exceeds its solubility.

The solution at first remains supersaturated and then, when in contact with the large surface area of ion exchange resin, severe $CaCO_3$ fouling was found to occur.

T. Y. YAN and coworkers developed an application for the SPIRACTOR cone (believed to be supplied by ENVIREX) to recirculate a slurry of calcite crystals to seed the supersaturated $CaCO_3$ solution ahead of the IX contactors. In this way, $CaCO_3$ is precipated from solution onto the calcite slurry in the SPIRACTOR and can be recovered in a cyclone from which a solids bleed removes $CaCO_3$ from the system.

The alternative of adding a $CaCO_3$ scale inhibitor to the solution is not favored because these chemicals might also inhibit U_3O_8 dissolution. Another alternative of using

pressurized IX systems is not favored because of the greater expense and reduced convenience.

The process requirements for the in situ leach facility are:

- Avoid additives.
- Must treat a large volume of water and yield a small volume of effluent.
- Must result in a minimal loss of $CO_3^{=}$.
- Must remove as much Ca^{2+} as possible.

The SPIRACTOR cone is designed for tangential feedwater and chemical inlets, and the water spirals upward to overflow as softened water at the top. A bed of seed crystals is charged periodically, and larger agglomerated particles are removed from the bottom. pH control and the technique whereby chemicals are added are critical for a successful operation.

When using milk of lime for pH adjustment, it has been found that 95% of the calcium and 75% of the magnesium are removed from solution. If, however, NH_3 is used, 95% of the Ca is removed but much less Mg.

Ca & Mg REMOVAL

The SPIRACTOR was tested at an in situ leach site by MOBIL OIL COMPANY. The system described by YAN (1983) was found to perform well.

REVERSE OSMOSIS

Normally, when relatively high levels of soluble $CaSO_4$ are present in water, reverse osmosis or electrodialysis processes cannot be used to achieve a high water recovery without running the risk of fouling the membranes.

RESOURCES CONSERVATION CO. of Bellevue, Washington, has developed a seeded slurry application of tubular reverse osmosis which achieves a 95% recovery from virtually $CaSO_4$ saturated feedwater. Be recirculating a gypsum slurry to the system, $CaSO_4$ precipitates onto the seed crystals rather than the membrane.

Acid mine water containing 400-450 ppm Ca and a total hardness of 1300 ppm $CaCO_3$ with 1600 ppm $SO_4^{=}$ was fed to a test unit which achieved over 95% recovery. Permeate contained only 10 ppm Ca; ie., there was a 97.5% removal of Ca^{++}. Ca in the concentrate solution remained at around 450 ppm, but the solids in the seed slurry ran 25% Ca, 55% $SO_4^{=}$, 0.23% Fe, and 0.6% Al.

More information on the seeded slurry process is available in chapters 14 and 24 and from:

CHAPTER 36

CHLORIDE Cl^- AND CHLORINE CL_2

Chlorides are present in virtually all water, being derived from natural origin (e.g., halite in rocks), from seawater contamination of ground water supplies, from salts spread on fields for agricultural purposes, from human or animal sewage, from industrial effluents including food processing, galvanizing plants, and oil wells and petroleum refineries. Chloride also gets into the water supply through water softening plants that use ion exchange. Disinfection of municipal drinking water using chlorine also adds chloride to water.

In the mining and metallurgical industry, chlorides can be introduced in water softening for boiler feedwater, in any metallurgical process employing chlorine or sodium chlorate, in zinc plants employing ammionium chloride fluxes or consuming flue dusts, and drosses and ash from galvanizing plants. Some ion exchange metal recovery plants use NaCl to regenerate resins. Hydrochloric acid can be used in some precious metals refining operations. Aquifers in many desert regions where mines are located often contain brackish saline water which is very high in chloride.

Chloride levels in fresh water supplies typically range from 10 to 100 mg/l. Seawater contains over 30,000 mg/l as NaCl, and some underground brine wells may be saturated at around 25% NaCl. Many geological formations were lain down as sedimentary rocks in the sea so it is not surprising that they contain chlorides that continuously leach into fresh water supplies. Typical sewage chloride content is 20-50 mg/l above the municipal water supply which accounts in part for the increase in salinity of rivers as they proceed to the oceans.

Many wastewater treatment plants are required to maintain a minimum residual chlorine concentration of 0.5-2.0 mg/l. Most plant operators control chlorination using the orthotolidene method of determining Cl_2 which has been shown to be biased on the low side resulting in much higher concentrations than necessary for adquate disinfection adding to toxicity problems in receiving waters according to the ONTARIO MOE (1979).

Total residual chlorine (TRC) concentration in 20 Illinois municipal sewage plant effluents ranged from 0.98-5.17 mg TRC/l according to SNOEYINK and MARKUS (1974). A similar survey of 22 plants in southern Wisconcsin found TRC values of 0.18-10.3 mg/l according to McKERSIE (1974).

Although chlorine and chloride levels are not frequently high in metallurgical effluents, the use and contemplated use of alkaline chlorination for cyanide removal makes the toxicity of chlorine of importance. It would be ludicrous to require chlorination to

detoxify cyanide in effluents if the chlorine levels in the treated effluent are themselves toxic. In this case, the treatment plant effluent may itself require further treatment to render the final effluent non-toxic.

Also, where great trouble and expense is devoted to making a mine-mill effluent non-toxic, it would be just as absurd to discard the effluents into a receiving stream before or after discharge of sewage plant effluents that contain residual chlorine levels that make the stream toxic to fish.

At the Beisa Mine in the Orange Free State, the minewater contains high chlorides and TDS values at 2,000 and 4,000 mg/l respectively. Much to the metallurgist's surprise, it was found that when this water is used in leach pulps, the filtration rate is about 20% faster than when Orange Free State Water Board water is used.

At the RUSTENBURG platinum refinery in the South African Bushveld igneous complex, it was found that during the recent drought, the chloride level in intake water increased at times to 150-200 ppm. Since this water is recycled within the plant, chloride levels were increased still further in the process solution with the result that pitting corrosion damaged the acid pressure leaching autoclaves which are fabricated from 316L stainless steel that cannot tolerate high Cl^- levels at elevated temperature and pressure. In the process, a two-fold increase in concentration of salt load occurs in the process water.

For this reason it is very important for this operation that high chloride levels in feedwater to the plant be avoided. If this is not possible, then a desalination plant will have to be considered to treat the water before it gets to the plant.

ENVIRONMENTAL AND HEALTH EFFECTS OF CHLORINE

Chloride as NaCl is an essential life supporting constituent, and no criteria exist for human toxicity. Excessive chlorides in water render it unsuitable for use in irrigation. Different crops have a wide range in tolerance to salinity.

The recommended upper limit for chloride in drinking water is 250 mg/l based entirely on taste, not on any known physiological hazards.

Chlorine, usually measured as total residual chlorine (TRC) includes Cl_2, hypochlorite (OCl^-), and hypochlorous acid (HOCl) which is toxic to fish and other aquatic species at sub ppm levels. Chlorine is used to disinfect water; in other words, it is highly toxic to microbiota (bacteria).

An ONTARIO MINISTRY OF THE ENVIRONMENT (1979) document provides numerous references to discussion on toxicity of chlorine in water.

The MICHIGAN DEPT. OF NATURAL RESOURCES (1971) reported effects on caged fish in several receiving streams below wastewater discharges. 96-hour LC_{50} for trout were found to be between 0.014-0.029 mg/l TRC. The same discharges were studied when chlorination was temporarily interrupted, and no mortality was observed. The toxicity effects of Cl_2 was observed for a distance of 1.3 km below the outfall. In addition, dechlorination with sodium thiosulfate eliminated toxicity in four-day tests with undiluted effluent.

ARTHUR, et al. (1975) studied the effect of chlorinated secondary wastewater treatment plant effluent containing only domestic sewage effluent. Daphnia magna was the most sensitive invertebrate species and died at a TRC concentration of 0.014 mg/l. Acceptable reproduction occured at 0.003 mg/l and below.

MARTENS and SERVIZI (1974) observed mortality of salmon in receiving streams at TRC concentrations as low as 0.02 mg/l. Lethal concentrations persisted in undiluted effluent for at least 50 hours.

REGULATORY LIMITS AND CRITERIA

Several reviewers of chlorine toxicity have recommended objectives for concentrations of TRC that would not adversely affect aquatic environments. BASCH AND TRUCHAN (1974) recommended maximum concentrations of 0.02 and 0.005 mg/l for warmwater and coldwater fish, respectively. The EUROPEAN INLAND FISHERIES ADVISORY COMMISSION (1973) has suggested objectives dependent on pH and temperature with an acceptable upper limit of 0.0004 mg/l TRC at pH 6.0 and 5°C to 0.121 mg/l at pH 9.0 and 25°C.

BRUNGS (1973) recommended objectives of 0.01 mg/l for warmwater fish and 0.002 mg/l for coldwater species and the most sensitive food organisms. Since then, however, several authors have refuted the distinction between cold and warmwater fish tolerance to chlorine. BRUNGS (1976) supports the objective for a total residual chlorine level of 0.002 mg/l for all species.

Chlorine generally does not appear on the list of contaminants to be controlled in mine-mill effluents. Surprisingly, chloride levels must be sampled and analyzed daily in effluent from each runoff water sedimentation pond on the property at HOMESTAKE MINING COMPANY's NPDES permit for their new McLaughlin operation in California.

The only case encountered during the course of this investigation where chlorine levels in effluents are regulated was in South Africa (1962) where TRC levels as Cl_2 are regulated in their general standard at 0.1 mg/l Cl_2 max. and in the special standard applicable to water discharged to trout supporting streams of Nil mg/l Cl_2 max.

FIG. 2. ANNUAL RAND WATER BOARD ABSTRACTION FROM VAAL SYSTEM 1935 TO 1979 AND PROJECTED ABSTRACTION 1980 TO 2000.

J.J.C. HEYSIKE and S.F. MCCULLOCH

Impact of mineral pollution in the water supply

PAST AND PROJECTED AVERAGE ANNUAL TDS CONCENTRATION AT THE RAND WATER BOARDS VEREENIGING INTAKE

LEGEND

PAST AND PROJECTED TDS CONCENTRATION

TREND OF INCREASE 5 YEAR MOVING AVERAGE

REPRESENT PEAK OR PROJECTED PEAK IN THE YEAR INDICATED

In South Africa, the TDS, including Cl^- in water from the Vaal Dam, has been rising steadily over the years to the extent that it is causing concern due to increased cost of corrosion. It is likely that new regulations will be introduced to restrict the TDS levels in effluents to around 250 milliSiemens/m which equates to about 2,000 ppm tds.

ANALYSIS FOR CHLORINE

A disposable rapid method for Cl_2 level analysis is available from:

PARK DAVIS AND CO.
11471 Vanowen Street
Post Office Box 9338
North Hollywood, CA 91609
(213) 765-7830

The test is known as the Water-Chex Color Comparison Test for chlorine at 0-11 ppm. It is an aseptic-thermo indicator which changes color proportionately to the Cl_2 level in the test solution.

The Water-Chex chlorine test kit is available in Canada from:

MILLER WILLIAMS HYDRONICS LTD.
4060 Fiarview Street, Unit 12
Burlington, Ontario L7L 4Y8
(Catalogue No. 00200)

This test is good down to 1 ppm which is still too high for meaningful effluent management.

Normally chlorine can be measured down to 0.1 ppm using a Hach kit available from:

HACH COMPANY
Post Office Box 389
Loveland, CO 80539
(303) 669-3050
Telex: 910-930-9038

REMOVAL AND DISPOSAL OF CHLORIDES

Two of the most frequently employed methods (according to PATTERSON, 1975) of controlling high chloride wastes involve techniques that more closely achieve ultimate disposal than chloride reduction per se. These methods are deep well injection and holding basins including solar evaporating ponds.

Methods for removing chloride ions from a waste stream include anion exchange, reverse osmosis, electrodialysis, and evaporation which are discussed in the chapters on desalination.

ION EXCHANGE

Chloride can be removed from water by strong base (type I and type II) resins. Usually high concentrations of chemicals are required for the elution and regeneration of the resin. A very interesting development employing hot water to elute resins loaded with Na and Cl ions has been reported by BOLTO (1975) and BALTO, et al. (1982). The CSIRO Sirotherm desalinating ion exchange process uses a mixture of magnetic polymers containing basic and acidic groups for removal of Na and Cl ions. The adsorption equilibrium is temperature sensitive based on the fact that water ionization is greatly enhanced from 25°C to 85°C. After years of research and development work and pilot testing, the second commercial scale Sirotherm plant is being installed at Leaderville, East Perth for startup in February, 1985. The Sirotherm process is designed specifically for removal of NaCl from water, and the results of the new installation will be most interesting. More information on the new installation can be obtained from AMDEL or from ICI, the manufacturers of the resin.

SIROTHERM

Technology for desalting brackish waters (after softening for removal of hardness, e.g., Ca, Mg, and $SO_4^=$ has been developed and demonstrated in Australia and described by BALTO (1975) and BALTO, et al. (1982). The first paper reports on how the problems of synthesizing polymers with adequate thermally regenerable capacity and rates of salt

uptake were overcome. Pilot plant trials were claimed to have confirmed a technically feasible and economically viable process.

A major CSIRO contribution to ion exchange technology has been the invention of resin systems which can be regenerated by washing them with hot water. Sirotherm resins are polymers of the weak electrolyte type which must always be employed as a mixture of polymers containing basic and acid groups. The sites for absorption of ions are formed from the uncharged groups by transfer of protons from the acidic to the basic species.

$$R'CO_2H + R''NR_2 + Na^+ + Cl^- \underset{\leftarrow \text{Hot}}{\overset{\text{Cold} \rightarrow}{=}} R'CO_2^-Na^+ + R''NH_2H^+Cl^-.$$

The overall equilibrium is temperature sensitive with the uncharged forms of the resins being favored at higher temperatures. The driving force behind the equilibrium is the large increase in the ionization of water that occurs on heating, about 30-fold from 25°C to 85°C. The additional protons and hydroxyl ions suppress the ionization of the weak electrolyte resins; the hot water can be looked upon as providing the acidic and basic regenerants which have to be separately added in the more conventional ion-exchange systems.

The main advantages of thermal regeneration are the low energy requirement (when low-grade waste heat is available) and the avoidance of chemicals for regeneration. The concentrated effluent contains only the salt removed from the resins, whereas in conventional IX processes, two to three times the stoichiometric amount of acid and alkali must be used to regenerate strong electrolyte resins.

BOLTO (1975) described the operation in its simplest mode where water containing, for example, 1,000 mg/l TDS is passed through a bed of Sirotherm resin until the average salt content of product is reduced to say 500 mg/l. Feedwater heated to 80-90°C is used as a regenerant. About 85% of the water passed through the column is obtainable as product, the remainder being disposed of as waste averaging 3,800 mg/l. Conceptually, the process is applicable to low salinity waters with up to 3,000 mg/l TDS where the contained salts consist mainly of NaCl, and a convenient disposal site for the concentrate exists.

BALTO (1975) describes various aspects of resin design as well as several early fixed-bed plants using the Sirotherm process, the largest being a 600 m^3/d unit at an ICI ammonia/soda ash plant at Osborne, near Adelaide, South Australia, as a primary step for boiler feedwater desalination.

It was concluded that Sirotherm was unlikely to compete with R.O. and EDR unless it could be operated as a continuous system.

Progress in the development of the Sirotherm process was described by BOLTO, et al. (1982), the latest developments being the development of thermally regenerable desalting resins in the form of magnetic microbeads and a continuous contacting system for desalination of feed water and resin regeneration. A prototype plant with a throughput of 1,000 m^3/d has been installed near Perth at Leederville to treat a sub-artesian municipal supply of water.

Advantages of Continuous Systems

- Reduced heat costs because of the smaller volume of regenerant.
- Greater yield of product water because of improved heat and mass transfer.
- Lower heat costs because both adsorber and regenerator are maintained at a constant temperature instead of cycling through hot and cold regimes.
- Simpler method of controling pH to optimize for buffering conditions.
- Simpler method of excluding or destroying oxygen dissolved in the water.

Magnetic Resins

Magnetic microbead resins were developed by CSIRO to obtain a simpler moving-bed system which exploits the more rapid reaction rates of much smaller resin particles. When magnetized microbeads with particle diameters as low as 100 microns (compared with normal beads of 300-1,200 microns) clump together, they form flocs containing 50 or more beads. These flocs settle considerably faster than individual beads and yet, in normal agitated condition, have kinetic properties that are little different from individual beads.

Magnetic resin beads are prepared in their simplist form by incorporating 10-15% by volume of magnetic oxidized ferrites into the reaction mixture. The kinetic and hydrodynamic properties were optimized, particularly in relation to their effect on engineering costs for a large scale counter current plant.

Adsorption Kinetics

GLUECKHAUF (1955) and others showed that reaction rates may be particle diffuson kinetics controlled in proportion to the distance to be traversed, i.e., particle radius divided by the volume or $r/r^3 = r^{-2}$. However, if the rate is controlled by film diffusion kinetics, then the rate is proportional to the surface area divided by the volume, i.e. $r^2/r^3 = R^{-1}$, and is profoundly affected by the degree of turbulence in the liquid phase. The rate of reaction can vary from one mode to the other in practice depending on the type of resin, size of bead, degree of agitation, and concentration of the solution. Where particle diffusion is dominant, the immediate past history of the bead can also be significant.

BOLTO, et al. (1982) go into some detail in showing the influence of particle size, turbulence, and hydrodynamics showing that for small magnetic beads, kinetics is more likely to be film diffusion kinetics controlled and that the rate of absorption can be greatly enhanced when a stirrer is added into the adsorption stages. Also, magnetized beads exhibited a faster settling rate than unmagnetized beads and as such, when magnetized, allowed a much greater upflow velocity through the adsorption contactor.

Magnetic filters are necessary to retrieve stray beads, and reference is made to high-gradient magnetic filters which use sharp-edged elements in a strong magnetic field which, however, allow non-magnetic particles to pass through the filter. This allows magnetic resin fluidized bed contactors to handle dirty waters and even dilute slurries.

The following diagrams from BOLTO, et al. (1982) illustrate the Sirotherm pilot plant arrangement incorporating a continuous flow and also a McCabe-Thiele diagram defining the Sirotherm pilot plant operation.

The pilot plant absorption unit consisted of 11 stirred stages in a vertical column, and the regenerator unit consisted of 17 perforated plate stages of which the first five stages served to preheat resin, and the center six stages were for regeneration followed by five stages for resin cooling.

LEADERVILLE (PERTH) DEMONSTRATION PLANT

The demonstration plant is installed outside Perth to desalinate wellwater with the following composition:

Raw Water

TDS	1,340 mg/l
Total Hardness (ppm $CaCo_3$)	119
Total Alkalinity (as $CaCO_3$)	153
pH	7.8
Temp °C	37
Na^+	444 mg/l
Cl^-	643 mg/l
HCO_3^-	187 mg/l

Product Water - Sirotherm

TDS	290 mg/l

Diagrammatic flowsheet of continuous "Sirotherm" process

Effect of stirrer speed on resin residence time

"Sirotherm" pilot plant McCabe-Thiele diagram

Concentration profile for treatment of a water simulating the Osborne application.

The demonstration plant has a diameter of 1.5m for 1,000 m^3/d throughout. The Sirotherm process requires softened feedwater which is achieved with a primary fixed bed ion exchange system. Major items in the plant are the softener columns, the Sirotherm adsorber, and the regenerator. Raw water, after softening and pH adjustment, passes up through the adsorber, overflows at the top, and passes through a strainer and a magnetic filter to trap stray resin beads.

A side stream of about 20% of the raw water passes through a heat-exchanger which recovers sensible heat from the effluent, then through an oil-fired heater to bring its temperature up to around 100°C' and then to the regenerator.

Hot effluent leaves via the heat exchanger which recoups heat to the incoming regenerant stream. A small flow of water is used to cool the resin after regeneration, and the same volume of hot effluent is allowed to pass upwards through the top section of the regenerator to heat the resin.

Both adsorber and regenerator are open topped and are virtually the same height. The resin transfer system has to operate over a head of only a fraction of a metre. To reduce attrition, a gas lift is used initially with a recirculating stream of nitrogen since air is inadmissible because of resin oxidation.

Resin transfer from the base of the regenerator to the adsorber is by gravity with small side streams of water recycling around these two loops to assist resin flow.

Provision has been made for sulfite dosing of the raw water to counteract any small quantities of oxygen that might leak into the system.

Pretreatment requirements for 'Sirotherm'

Although the concept of regeneration with hot water is enticingly simple, the ionic equilibria involved are quite complex, especially when there are many types of ions present in the feedwater and particularly if they are capable of buffering action. Recent understanding of the physical chemistry involved has revealed that it is not necessary to remove competing buffers as a pretreatment step as had been initially thought in the case of bicarbonate--a simple pH adjustment of the hot and cold feedwater being all that is necessary.

One aspect of the resin equilibria which is not readily controllable is the high selectivity of the weak base functionality in the form of carboxylate groups for divalent and higher charged cations. Because of this, it is difficult to achieve effluent removal of both Ca^{2+} and Na^{+} salts in the same column.

The most economic use of the Sirotherm resin is to remove hardness cations separately by means of a brine-regenerated strong acid ion-exchange resin so that the desalting step is carried out on a fully softened water. However, BOLTO, et al. (1982) do claim that suitably tailored resins can be applied successfully to predominantly hard waters in a hot-water regenerated softening process. This has two advantages over conventional ion exchange softening: an equivalent amount of anions are removed as well as hardness cations (in the normal process calcium is replaced by sodium, and there is no reduction of TDS); and there is no heavy excess of salt in the effluent.

For surface waters containing oxygen, it is necessary to remove dissolved oxygen to prevent irreversible degradation of the amino groups which are the weak base active sites on the resin. These would be slowly oxidized by oxygen at the hot regeneration temperature. Chemical dosing with sulfite is the preferred method for oxygen removal since experience with vacuum de-aeration has shown this method to be less reliable.

Sirotherm resins are fairly resistant to organic fouling by dissolved color bodies. Small molecules are absorbed and desorbed again by hot water. Very large molecules do not enter the resin structure. Medium sized color molecules must be removed using a resin trap.

In contrast with most other desalination processes, preclarification of the feedwater is not needed for a magnetic resin system. In almost all cases, resin can be regenerated even if it has become contaminated by organic or color fouling. However, oxygen oxidation of the amine groups is irreversible.

CONCLUSIONS ON "SIROTHERM' PROCESS FOR AMD TREATMENT

1. Sirotherm as described by BOLTO (1975) and BOLTO, et al. (1982) does not appear applicable to TDS removal from AMD as it is necessary to remove "hardness" ions from feedwater to Sirotherm, i.e., Ca, Mg, SO_4.

2. Sirotherm appears applicable for NaCl removal from soft wellwaters in the range 1,000-3,000 mg/l TDS.

CONVENTIONAL IX NaCl REMOVAL

Ion Exchange demineralization is routinely used in treatment of boiler feed waters, and the results of several ion exchange desalination installations treating municipal waste plant effluents are reported by CULP, et al. (1978).

Typical chloride removal of efficiency in ion exchange processes appears to be in the 90-95% range at the levels encountered in wastewaters.

It should be remembered that in most ion exchange processes, concentrated eluants are used, often concentrated brine or acid which require special disposal measures such as ponding or deep well disposal. More often than not, however, the ion exchange regenerating solutions are discarded to the sewer or, in the case of mine-mill complexes, to the tailings pond. Usually this does not present a problem.

Chloride removal from waste waters has been discussed by HIGGINS (1969) who developed the Chemseps loop continuous plugflow ion exchange system. HIGGINS points out that the removal of strong acid and acidic ions such as chloride, fluoride, and phosphate anions requires a weak base type anion exchange resin. Strong-base anion exchange resins are more selective for common ions such as hydroxide and bicarbonate than for chloride and thus are less selective for chloride removal.

When resins are exhausted in a chloride removal plant, salt exchange capacity can be regenerated with weak alkali-ammonia solution according to HIGGINS (1969), but this introduces the question of what to do with the regenerant waste containing ammonium. Cost data reported by HIGGINS (1969) and others in CULP, et al. (1975) would by now be largely obsolete. In 1970, the capital cost for a 100,000 gallon/day anion exchange plant treating a 1,500 mg/l Cl^- waste was estimated at $169,000, and operating costs of U.S. $0.27/1000 gal. have been projected by the U.S. EPA (1971).

Several HIGGINS loops have been installed for boiler feed water dimineralization including one at SIMPLOT CHEMICAL COMPANY LTD., Brandon, Manitoba, in 1967. TDS in brackish feedwater was claimed to have been reduced from 1,800 ppm to less than 3 ppm. More information can be obtained about the HIGGINS loop from:

ELECTRODIALYSIS/ELECTRODIALYSIS REVERSAL/REVERSE OSMOSIS

Electrodialysis and reverse osmosis have and are used for chloride removal from water. A notable application is for recovery of potable water from seawater, and numerous huge reverse osmosis plants have been installed for the purpose in the Middle Eastern oil states, in parts of Florida, on Malta, and elsewhere. This application falls under potable water rather than the subject at hand, however.

It is not considered likely that reverse osmosis or electrodialysis would be found economically attractive for removal of chloride from minewater or metallurgical effluents except in very special cases. No such installations were identified during this investigation. R.O. and EDR desalination are discussed in the chapters on Desalination.

EDR has been employed to treat 6,000 m^3/day feedwater for rougher demineralization of feedwater from 300 ppm to 40 ppm TDS ahead of ion exchange at the Kriel power plant of ESCOM outside Johannesburg, South Africa. This unit is an IONICS EDR plant installed by:

PROCESS SYSTEMS PTY LTD.

Ralph A. Jones
Managing Director

IONICS INCORPORATED
65 Grove Street
Watertown, MA 02172
(617) 926-2500
W. E. Katz

The capital cost for a plant of this size including building would be around R3.0 million and operating costs about R0.35/m^3 ($0.17/$m^3$).

GARLING (?) of UNC TETON EXPLORATION DRILLING, INC., Casper, Wyoming, described an evaluation of electrodialysis for process water treatment for in situ mining of uranium. A 30,000 gpd (114 m^3/d) IONICS test unit was tested at the Teton-Nedco Leuenberger Research and Development plant in Wyoming. The dual-state unit was expected to yield 665 mg/l TDS water from feed of 2,650 mg/l with a water recovery of around 80%.

Chloride in the feedwater of 432 ppm was reduced to 61 ppm giving a rejection of 85.9% with rejection of gypsum in excess of 92%, although chloride removal was not the primary objective of the test.

PATTERSON (1975) describes several electrodialysis plants for chloride removal with saline and brack water in municipal water supply. In one plant (SMITH AND EISENMANN, 1964), chlorides were reduced from 115 to 80.5 mg/l which is not exactly impressive. KATZ (1968) reported chloride reduction from 122 to 58 mg/l. Capital costs for EDR installations are proportional to plant size from 1.0 mm gpd through 10 mm gpd.

PATTERSON (1973) showed some now ten-year-old data for R.O. removal of chlorides from various types of water as reported by SHIELDS (1972), NUSBAUM, et al. (1972), and CRUVER and NUSBAUM (1974). Additional cost data are provided in the chapters on desalination.

A company with recent experience in water desalination of all kinds that would be able to provide guidance on chloride removal is:

RESOURCE CONSERVATION COMPANY

Reams Goodloe

Table 16. Reverse Osmosis Treatment for Chloride and TDS.

Source	Volume (gpd)	Chloride (mg/l) Initial	Chloride (mg/l) Final	TDS (mg/l) Initial	TDS (mg/l) Final	Ref.
Brackish ground water	24,000	96	59	1800	155	19
Brackish ground water	150,000	351	32	2100	170	19
Brackish ground water	50,000	2020	170	4580	310	18
Sewage treatment plant effluent	10,000	280	15	756	24	20
Sewage treatment plant effluent	—	209–378	14–44	757–1170	49–92	21

Source: PATTERSON (1975)

Based on evidence so far, RANDOL INTERNATIONAL LTD. would favor the RCC seeded slurry reverse osmosis process wherever water is scaling in character or high in $CaSO_4$ content. The seeded slurry R.O. process is still to be demonstrated on a commercial scale, however.

SEALED CELL ELECTRODIALYSIS

A most innovative new electrodialysis desalination device which uses pulverized carbon electrodes as an electron pump was demonstrated at the World Desalination Conference in May, 1983, in Venice, Italy.

Electro-osmotic ion transfer through the membranes is used. Desalination of NaCl solutions was demonstrated as follows:

C_f Feed mg/l	C_p Product mg/l	Output $m^3/m^2/d$	DC Energy kWh/m^3	Brine mg/l	Volts/ Cell Pair Volts
2,500	500	1.81	1.04	86,000	0.7
1,000	430	4.2	0.29		0.7
500	10	1.05	0.63	47,000	1.0
485	50	2.36	0.34		1.0
1,000	50	1.40	0.20	26,000	1.5
100	10	2.08	0.12	23,000	1.0

r = Recovery
V_b = Brine Volume
V_o = Feed Volume

$$r = 1 - \frac{V_b}{V_o} \cdot \frac{V_b}{V_o} = \frac{C_f - C_p}{C_b - C_p} - \frac{C_f - C_p}{C_b}$$

In porous carbon electrodes, high charging currents were reported; the double layer capacity on an internal area of 500 m^3/g-800 m^3/g leads to electrosorption of Na^+ on the cathode and Cl^- on the anode up to 0.6 meq/g. In the new system, effective periodic charge reversal of c electrodes is achieved by circulating a suspension of carbon black or activated charcoal between anode and cathode compartments, and continuous current is maintained by circulating carbon between the electrode compartments.

The interesting aspect of the sealed cell electrodialysis process is the extremely high concentration of brine achieved and the low energy consumption indicated in the results above.

DISPOSAL OF BRINES

Concentrated chloride wastes, for example, ion exchange eluates, or reverse osmosis concentrate have been disposed of in holding ponds, evaporation basins or deep well disposal.

PATTERSON (1975) mentions deep well disposal for a chemical industry wastewater containing 10-15% NaCl at volumes of 500-600 gpm. This system was described by HENKEL, H.O. (1966). THE INTERSTATE OIL COMPACT COMMISSION (1968) also reviewed the Subsurface Disposal of Industrial Wastes. Since then deep well disposal has become a relatively commonplace occurrence and injection pressures of 200-5000 psi have been recorded for chloride wastes by GLOYNA and FORD (1970).

Most states and the petroleum industry employ experts in deep well disposal of oil industry wastes. There remain many questions as to the environmental safety of deep

well disposal and THE INTERSTATE OIL COMPACT COMMISSION (1968) concluded then that it could create pollution problems far more severe than those being corrected.

During the course of this investigation, deep well injection technology as a means of disposal was not investigated although it was often mentioned as one possible answer to the concentrated waste disposal problem. One person specializing in this aspect and interested in groundwater contamination problems is:

EDICIA M. RODRIQUEZ
State of Nebraska
Oil and Gas Conservation Commission
Box 399
Sidney, NE 69162

Edicia Rodriquez may be able to steer engineers to more senior sources of expertise and information on deep well disposal of wastes. Based on data provided by PATTERSON (1975), the cost of deep well disposal is not very exorbitant, ranging from $75,000/year to $100,000/year to dispose of one million gpd at 0 to 1,400 psi with capital costs varying in 1975 from $225,000 to $270,000.

It is known that DuPONT de NEMOURS AND COMPANY uses deep well injection for disposal of a ferric chloride effluent stream generated at a large new titanium oxide pigment plant in the southern U.S.A.

PONDS AND BASINS

Holding ponds are used to store wastewater in times of low-receiving stream flow with gradual wastewater release to the stream in high-flow periods at rates necessary to maintain acceptable stream quality standards.

Solar evaporating ponds use solar evaporation to avoid the release of wastewater to receiving streams. Disposal by evaporation is limited by geographical location, climate, and land availability as discussed by U.S. DEPT. OF THE INTERIOR (1967).

JONES (1961) reported the use of a holding pond and controlled discharge of a chloride waste. The holding basin to contain an effluent containing 9% Cl^- with a capacity of 150,000 ft^3 cost about $1 million in 1958, including land.

BENTEL and JAMES (1983) described the design of evaporation ponds for the disposal of high chloride minewater from gold mines in the Orange Free State Goldfields of South Africa. These ponds are not lined.

They concluded that evaporation ponds are by far the least expensive way of disposing of brack water and are much more economical than the desalination alternative. More information was requested (but not provided) from:

OCCURRENCE OF CHROMIUM IN THE ENVIRONMENT

Chromium is a relatively common element geologically, but the chromate and dichromate forms are very seldom found except in polluted water. The median value for public water supplies studied by DURFOR and BECKER (1964) was 0.43 mg/l as Cr, and, for North American rivers, the median reported by DURUM and HAFFTY (1963) was 5.8 mg/l.

Chromium has several possible oxidation states. Thermodynamic data by LATIMER (1952) show that Cr^{3+} and Cr^{6+} species are stable in water, and that solubility of chromium is less than 0.5 mg/l Cr only between pH 8.0 and pH 9.5 and in solutions having a slightly lower eH than imparted by saturation with atmospheric oxygen.

The anionic species dichromate $Cr_2O_7^{=}$ and chromate $CrO_4^{=}$ are relatively stable in groundwater environments. In strongly reducing environments below pH 8.0, the predominant form is the complex cation $CrOH^{2+}$ according to HEM (1970).

Chromium as Cr(VI) can enter aquatic systems from the production and use of explosives, paper, dyes, paints, plated materials, and tanning. As Cr(III), chromium is present in glass, ceramics, photography processes, and textile dying mordants.

Plating wastes have been the most common source of chromium contamination to municipal and receiving waters in the U.S.A. and may still be so in some countries. This industry uses chromium as dichromate (the more enviromentally undesirable form) and at relatively high concentrations.

Another common use of chromate has been in corrosion control for cooling towers and boiler tubes in steam boiler plants for power plants and also for mining and metallurgical operations. This use, as well as more recent trends to limit its use or to reduce the dosages of chromium used, is reviewed in the NALCO WATER HANDBOOK (1979). Chromate is an exceptionally reliable corrosion inhibitor and formerly was applied in concentrations of 200-300 mg/l as $CrO_4^{=}$ at pH 60-7.

This treatment was also found effective as a scale inhibitor. ONTARIO MOE (1979) and SHEPHERD & JONES (1971) mention cases where up to 1700 mg/l of chromium as dichromate is used in this way. Subsequently, chromate at 20-30 mg/l $CrO_4^{=}$ was combined with other inhibitors such as zinc and polyphosphonate, also at pH 6-7, with even better results. Environmental pressures have resulted in the development of anti-corrosion treatments using only 10 mg/l $CrO_4^{=}$ in a recirculating system, but these require more careful pH control, and the addition of biocides to prevent uncontrolled microbial activity.

Environmental pressure has resulted in the development of more advanced corrosion prevention additives such as organo-zinc combinations and or organo-phospherus additives. Experts in this highly specialized field include:

CALGON CORP.
Post Office Box 1346

Dr. Frank Daniher
Dr. Ben Boffardi

Chrome or processing plants - e.g., the small number of chrome chemical producers and possibly chromium ferro alloy producers are possible industrial sources of chromium contamination of water, i.e., locations where treatment technology may be found. However, these were not investigated in this survey.

A discussion of chromium introduction to the environment is provided by ONTARIO MOE (1979).

CHROMIUM IN THE MINE-MILL ENVIRONMENT

The mineral processing industries use dichromate for galena depression from lead-copper sulfide mineral separation in flotation plants although its use for this purpose has, to a large extent, been reduced in recent times. Flotation tailing effluents formerly could be discarded without concern for the environment. More recently, the emphasis has been placed on recycling as much of this water as possible to reduce the volume of effluent requiring treatment. If water containing dichromate ions is returned to the front end of the process, there is the danger of depressing mineral values in the primary flotation step which would be undesirable. Consequently, alternative flotation circuit arrangements have been sought where possible. In 1985, the Newmont Mining Corp. was served with three law suits totalling $150 million in connection with hexavalent chromium contamination of water at their Idarado Mine in Colorado which shut down six years ago.

GROVE, et al. (1979) of the USGS, Denver, reported data on 38 groundwater and 25 near surface water samples analyzed for hexavalent chromium. These were taken within the city limits of Telluride during October, 1978. Twenty-four groundwater samples and six surface water samples contained more than 50 ug/l hexavalent chromium. Hexavalent chromium in groundwaters ranged from 0-2,700 ug per l and, in surface waters, from 0-160 ug/l. More information may be available from:

U.S. GEOLOGICAL SURVEY WRD
Post Office Box 25046, MS 413
Denver Federal Center
Denver, CO 80225
(303) 236-4997
David B. Grove

LEVINS (1979) reported 10-50 mg/l Cr in the decanted acid tailings/raffinate effluents from leached Jabiluka uranium ore in Northern Territory, Australia, where Alligator Rivers-type ores contain some chromium.

Another potential source of chromium in water could be expected to be the chromite mining and processing industry although this was not investigated. Water in and around the Bushveld Igueous complex of the Transvaal would be a good place to examine this possibility although high chrome content soils and resources in California and Montana

could also be included in this category. The Bushveld complex contains about 80% of the world's chromite reserves.

The PEDCO (1983) Report which surveyed the composition of water at various points in many mines and mills covering a very broad cross section of the industry as well as acetic acid leachates of solid materials encountered in mines, mills, and tailings, presented data in a comprehensive report. The data for chromium indicated that, although chromium is present in the solids at many of these mines in tailings, ore, or sediments, there are few cases where the level exceeds 0.100 mg/l in the effluent or leachate. Typical concentrations range between 0.010 and 0.90 mg/l Cr (total) in effluents and leachates.

The table on the following page lists all cases where Cr (total) in an effluent, water, or acetic and leachate exceeded 0.10 mg/l.

The PEDCO (1983) data indicates that Cr very seldom exceeds 1.0 mg/l in water and leachates from mine/mill tailings material. In all the hundreds of samples analyzed, Cr exceeded 1.0 mg/l only twice and exceeded 0.100 mg/l only about thirty times.

It is concluded that if a limit of 100 ppb Cr were to be set, most mines and mills would be able to comply without installing a water treatment plant. Tailings pond liquid from ten operations exceeded 0.100 mg/l and minewater from five. It is also concluded that if 0.05 ppm Cr average is set as a limit for effluents, then about half the operations involve liquids that exceed this limit. Setting a limit of 0.24 ug/l, which is the EPA water quality objective for hexavalent chromium in freshwater, would be extremely difficult to meet for any mine or mill using hexavalent chromium.

Unless the U.S. chromium standard objectives are relaxed, many mining operations may, in the future, have to treat effluents for chromium removal to meet anticipated effluent discharge regulations.

THE USE OF DICHROMATE IN FLOTATION PLANTS

A common arrangement in flotation plants treating complex sulfide copper-lead-zinc ores is to float a copper-lead rougher concentrate which is then separated by depressing galena and floating a copper sulfide concentrate, with or without a regrind of the rougher concentrate. Addition of dichromate ions has been a popular way of depressing galena in this process; for example, as referred to in the trip report on HEATHE STEEL in Appendix I, which adds 130 mg dichromate per ton of ore treated. A sometimes used alternative is to depress copper sulfides with cyanide and to float the galena.

Typical chromium levels encountered in flotation plants have been reported in a proprietory report by a major engineering company at 0.001-0.1 mg/l. Virtually no other data on Cr levels in flotation plant effluents were encountered during this survey. Many operations visited do not use flowsheets that require dischromate use. Most often the nature of the ore determines the appropriate flotation plant flowsheet and whether or not dichromate use is metallurgically advantageous. The Newmont Mining Company employed dichromate as a flotation reagent at their Idarado Mine outside Telluride, Colorado, for a brief period some years ago. Details of actual damage caused by this chromium use, if any, have yet to emerge, however.

It is believed that EXXON MINERALS COMPANY has considered the use dichomate as a galena depressant for their CRANDON operation in Wisconsin. In this case, as much water as possible will be reclaimed from the tailings pond and recycled. Dichromate has not been an item of major concern as it was anticipated that it would quantitatively be converted to trivalent chromium in the tailings pond. In view of 1985 litigation against the Newmont Mining Company, it can be expected that the use of dichromate at Crandon may be reconsidered.

It has been pointed out that in operations where thiosulfate is present in tailings ponds and in reclaimed water and where the pH is allowed to drop to pH 3-4, any excess dichromate ions should quantitatively be reduced to trivalent chromium. Often, when thiosulfate is present, pH will automatically drop to these levels as thiosulfate oxidizes to $SO_4^{=}$, particularly in warm seasons.

Detailed work by CANMET and NORANDA RESEARCH found that in winter about 60-70% of the thiosulfate in water is oxidized. In summer, about 95% of the thiosulfate can be oxidized in a holding pond. According to CANMET, NORANDA, and others, thiosulfate is generated when ores containing reactive sulfide minerals, particularly certain types of pyrrhotite, are ground at a high pH in mills to which lime or soda ash have been added. There is a wide range in the degree of thiosulfate generation from one mine-mill complex to the next. For example, BRUNSWICK MINING in New Brunswick generates very high levels of thiosulfate, but NORANDA MINES, MATTABI, does not. Thiosulfate generation

and removal or inhibition is the subject of a major study by CANMET and NORANDA, and preliminary data indicates that the understanding of this phenomenon is far from simple.

BRUNSWICK MINING is reputedly working on a new simplified flotation arrangement that reduces the use of SO_2 and allows for much greater use of recycle water and a smaller volume of effluent.

WASSERLAUF and DUTRIZAC (1982, 1983) reviewed CANMET's project on the chemistry, generation, and treatment of thiosalts in milling effluents. Much more information is however available in CANMET files, and an excellent picture of the phenomena can be obtained through consultation with those who have been devoting years to this investigation:

Dichromate addition for galena depression is or has been used by, amongst others, the NEWMONT MINING COMPANY, BOLIDEN MINERAL AB, HEATHE STEEL, and at the Missouri Lead Belt. NEWMONT indicates that in their experience one cannot rely on thiosulfates in the tailings pond to convert hexavalent chromium to the trivalent form adequately to avoid metallurgical problems when the water is recycled. BOLIDEN pointed out that the thiosulfate reaction with Cr(IV) may be the reason for some otherwise unexplained Cr(VI) to thiosulfate ratios found in their tailings pond water. Copies of letters from NEWMONT and BOLIDEN MINERAL AB provide further interesting comments and the names and addresses of contacts in these companies through whom this point could be followed up further if needed.

It is concluded during this RANDOL investigation that very limited detailed knowledge is available on the behavior and control of hexavalent chromium in metallurgical circuits.

Dear Hans:

Many thanks for your letter of April 20, 1984 and the copy of Randol's report "CIX-RIP For Uranium Recovery".

With respect to hexavalent chromium in flotation, I note the following: You are probably right that thiosulfate ions are formed during the grinding of sulfide ores in an alkaline pulp. The problem is that sodium dicromate is not added to this circuit. It is added to the copper/lead separation circuit where little or no thiosulfate is present. Based on our experience, I think that it is dangerous to rely on the reduction of hexavalent chromium to trivalent chromium by means of thiosulfate in the tailings dam. It most certainly did not happen in our case.

When I checked into this matter about a year ago, I talked with Norman Holme, Chief Metallurgist, Cyanamid who noted that in the Missouri lead belt where dichromate is used for copper/lead separation, the water is always kept separate except at the Magmont mill where only 25 percent water is recycled. Deleterious results were experienced in the early days of operations in the Missouri lead belt.

Dichromate is a potent depressant even in very small quantities so that apart from the toxicity problem, one can expect problems in the flotation plant. In our opinion, the copper/lead separation circuit should be clearly isolated from the rest of the circuit to prevent these problems.

Best personal regards.

Sincerely

Leonard Harris

Dear Mr von Michaelis,

Thank you for your note on Cr (VI) reduction by thiosulphate ions. This has not been studied or even observed by us. We know however that thiosulphate could reduce Cu (II) to the monovalent or even elemental state. This is in fact what we think happens in the SO_2-promoted flotation processes.

Your idea actually made us consider this phenomenon being behind some so far unexplained Cr (VI) to $S_2O_3^{2-}$ ratios being observed in our effluent streams.

Thank you once more. We look forward to seeing your final report.

Yours sincerely,

Levels of chromium (VI) at which it interferes with bulk or semi-bulk flotation efficiency when present in recycled water has not yet been clearly determined or reported in the literature although the levels will be low.

ENVIRONMENTAL IMPACT OF CHROMIUM

Chromium at low concentrations may be a nutrient for plants and animals. Although not proven to be essential for plants, low concentrations in soil and water appear to stimulate growth of terrestrial and aquatic species (ONTARIO MOE, 1979). A United States National Research Council panel on chromium concluded that chromium must be considered an essential element for mammalian health (NRCUS, 1974).

Toxicity of chromium to aquatic biota is quite variable and depends on the species tested. Daphnia magna reproduction and activity were inhibited by 330 ug/l chromium.

A series of unpublished studies by BENOIT and PICKERING reported in Water Quality Criteria, 1972 (NAS/NAE, 1973) demonstrated "safe" concentrations based on reproduction of 300,600 and 1,000 ug/l hexavalent chromium for rainbow trout (Salmo gardineri), brook trout (Salveliorus fontiralis), and fathead minnow respectively.

ONTARIO MOE (1979) cites references showing that the acute toxicity levels of Cr(III) is higher than that of Cr(VI).

Chromium levels in dressed samples of fish tissue were found by UTHE and BLIGH (1971) to range from less than 0.017 ug/g to 0.034 ug/g wet weight indicating that chromium may be lower in flesh than in the whole fish which was found to be in the range 0.9-16 ug/g by LUCAS and EDINGTON (1970). There was no variation in chromium concentrations in the flesh of fish taken from Lake Erie and those from a lake in Manitoba which was not affected by industry.

Experimental exposures indicate that Cr(VI) was taken up from water at concentrations as low as 1 ug/l. At 2,500 ug/l, uptake was via the gills, and metal occurred in the spleen, posterior gut, and other organs in preference to the muscle tissue. It is concluded that chromium uptake in fish is not a potential problem for species that eat fish according to ONTARIO MOE (1979).

The ONTARIO MOE (1979) review found that no objective for chromium concentrations in fish are needed. Based on algal growth response to chromium and the mortality of chinook salmon, a concentration of 100 ug/l should protect aquatic life. This figure in unfiltered water is also used by ONTARIO MOE (1978) as an objective.

The U.S. EPA (1980), on the other hand, set criteria for hexavalent chromium in freshwater at 0.29 ug/l as a 24-hour average concentration and 21.0 ug/l as maximum permissable concentration.

The U.S. EPA (1980) also set a maximum permissable concentration for Cr(III) as a function of hardness where the maximum permissable concentration (MPC) is computed as follows:

$$MPC = e^{(1.08[\text{in hardness}] = 3.48)}$$

This computes out as illustrated in the graph on the following page.

Elsewhere, CANADA (1979) and QUEBEC (1977) set a recommended objective of 40 ug/l total Cr.

The U.S. EPA set a marine water criteria of 18 ug/l for hexavalent Cr for 24-hour samples and a MPC of 1260 ug/l.

It can be concluded from available data that:

- The U.S. EPA (1980) criteria for 24-hour average concentration for hexavalent chromium in fresh water of 0.24 ug/l appears to be stricter than called for by the data.

- Toxicity of chromium compounds in the marine environment occurs at much higher concentrations than in fresh water.

- Chromium in aquatic environments is less toxic than many other metals, and the toxicity of trivalent chromium appears to be affected by hardness of the water which does not change the toxicity of hexavalent chromium.

SAMPLE PRESERVATION FOR Cr(VI) ANALYSIS

STOLLENWERK and GROVES (1985) report the potential loss of hexavalent chromium under common sample-preservation techniques. The standard preservation technique for water samples analyzed for Cr(VI) consists of filtration through a 0.45 u membrane, acidification to below pH 2, and storage in plastic bottles. Batch experiments were conducted to evaluate the effect of hydrogen ion (H^+) concentration and temperature on the reduction of Cr(VI) to Cr(III). Results showed that significant reduction of Cr(VI) to Cr(III) can occur at pH below 2 and that the rate of reduction increases with decreasing pH and increasing temperature. Reduction of Cr(VI) is inhibited by storing the sample at 4°C'. The authors indicate that water samples collected for the determination of Cr(VI) need to

EFFLUENT REGULATIONS - CHROMIUM

In very few of the mining and milling operation permits reviewed was chromium even listed. The only two cases identified are for HOMESTAKE MINING COMPANY operations at Lead, South Dakota, and the new McLAUGHLIN project in California. The latter is permitted for zero-discharge except for runoff waters collected on the site.

HOMESTAKE MINING COMPANY

	Lead, SD NPDES	McLaughlin NPDES Permit 30d Ave.	Daily Max.
Cr Total	0.85 mg/l	0.05 mg/l	0.10 mg/l

Surprisingly, no examples of permits for flotation plants recovering copper, lead, and zinc ores were encountered which stipulated limits for chromium.

Chromium is considered by the Environmental Protection Agency to be a hazardous substance according to BAKER AND BHAPPU (?). They listed a New Mexico Water Quality Control Commission regulation promulgated on August 27, 1971, forbidding discharge of an effluent containing in excess of 0.01 mg/l total chromium.

On February 7, 1984, EPA (1984) published a revised Ambient Water Quality Criteria document for chromium in which they proposed several changes in the criteria to better reflect real world situations. These changes concern the analytical species to be controlled and the time period over which the parameter average concentration is to be measured. The analysis is restricted to "active" trivalent chromium and dissolved hexavalent chromium, and it was proposed to calculate the criteria average on a 30-day basis rather than the previous 24-hour time frame. The American Mining Congress is working on further clarification and modification of the EPA (1984) proposed new water quality control criteria for Cr. New terms such as family mean acute values (FMAV) and species mean acute values (SMAV) have been introduced into the regulatory language. In

industrial waste disposal, the present EP Leach test limit for trivalent chromium is 5 ppm. It is reputed that the EPA is now getting ready to lower these limits significantly. This could be important when final regulations for mine/mill waste disposal are formalized.

Public water supply criteria for chromium in the U.S.A. are as follows:

	Cr (Total)	Cr(VI)
U.S. EPA (1972)	50 ug/l	
U.S. EPA (1976)	50 ug/l	
U.S. EPA (1980)		50 ug/l
CANADA (1979)	100 ug/l	
CANADA (1980)	100 ug/l	
ONTARO (1978)	50 ug/l	
QUEBEC (1977)	50 ug/l	
ALBERTA (1977)	50 ug/l	
SASKATCHEWAN (1975)	50 ug/l	
MANITOBA (1979)	50 ug/l	
NEW MEXICO (1971)	10 ug/l	

Regulation changes concerning chromite levels in effluents are of interest to manufacturers of chrome chemicals whose market may be affected, and some update on regulatory trends may be available from:

On problem with chromium and the EP Leach Toxicity test is that under the conditions of the test (namely a leach by acetic acid at pH 5, both chrome (III) and Cr(VI) are soluble. Cr(III) is almost insoluble at pH 7-10, but Cr(VI) is soluble throughout the whole pH range.

The EP Toxicity Leach test can be overcome if excess alkali is added to the waste to prevent a pH drop when acetic acid is added.

In South Africa (1983), a proposed standard of 0.5 ppm total chromium and 0.05 ppm hexavalent chromium has been proposed for effluents discharged in the Witwaterstrand area.

Inquiries to the Colorado Dept. of Health regarding chromium regulations in the state and how they are enforced were referred to Carol Russell, who was unable to discuss details of the state's approach to enforcement of regulations regarding chromite contamination in view of the pending CERCLA (Superfund) litigation which she is directly involved in.

METHODS FOR REMOVING CHROMIUM FROM EFFLUENTS

Several methods are in use for removal or reduction of chromium from solutions. Selection of a suitable process undoubtably depends on the level of chromium in the effluent to be treated and the level that must be achieved before the effluent can legally be discharged. Another aspect of recent interest is how to remove chromium (VI) from groundwater once contamination has occurred.

No case was encountered where mine and mill tailings water is treated specifically to remove chromium as Cr(III), Cr(VI), or total chromium although LEVINS (1978) showed that by adding lime to adjust the pH of Jabiluka uranium mill effluent (tailings decant/raffinate mixture), chromium was dropped from 10-50 mg/l to 0.3 mg/l. Several other metal contaminants and gypsum were also reduced in this way.

In other industries, chromium removal is practised, and some of these processes are reviewed here. Also, in the literature, several examples of newer processes were encountered which claim to be able to remove chromium either very specifically or at an economical cost.

PATTERSON (1975) points out that reduction of hexavalent chromium from a valence of +6 to +3 and subsequent hydroxide precipitation of the trivalent chromium ions is the most common method of hexavalent chromium removal. He points out that ion exchange is also being used to treat chromate and chromic acid wastes in the metal finishing industry.

REDUCTION

The standard reduction treatment is to reduce the waste stream to pH 3.0 or below with sulfuric acid and to convert hexavalent chromium to trivalent chromium with a chemical reducing agent such as sulfur dioxide, sodium bisulfite, metabisulfite, hydrosulfite, or ferrous sulfate. Trivalent chromium is then removed, usually by precipitation with lime, according to MACDOUGALL (1954) and BESSELIEVRE (1969).

ROUSE (1985, personal communication) suggests that the best way to remove Cr(VI) from groundwater is to precipitate it in situ by adding pyrosulfate ions to reduce it to a form that can be geochemically immobilized.

The reduction of hexavalent to trivalent chromium is not 100% effective, and the amount of unreduced hexavalent chromium depends on the time allowed for the reaction, pH and concentration, and the type of reducing agent employed. The interdependence of variables is shown in the following diagram:

Effect of treatment pH and reaction time on conversion of hexavalent to trivalent chromium. [From Beevers (15), courtesy of Metal Finishing Journal.]

Sulfur dioxide is the most popular reducing agent used in the treatment of chromium in industrial wastes because it is relatively cheap according to PATTERSON (1975) and STONE (1972). SO_2 for Cr(VI) reduction at low pH has been in use at a BOEING plant, according to HALSE, et al. (1960).

In this process, a waste was reduced to pH 2.5 with sulfuric acid before reduction.

SO_2 used to treat chromic acid plating bath wastes at an average waste flow of 40 gpm for 20-30 minutes yielded a residual hexavalent chromium level of less than 1.0 ppm according to SHINK (1968). Although this and several other references describe Cr(VI) reduction, the question arises whether chromium can be reduced to the much lower levels demanded for mine-mill-tailings effluents and at the much larger flowrates typical of these systems.

CURRY (1972) pointed out that hexavalent chromium levels of 0.01 mg/l can be achieved by reduction at pH 2.5-4.0.

LAVIN and LAVIN (1972) described a fully automated continuous flow chromate waste treatment system for reducing hexavalent chromium to below 0.05 mg/l. The cost of the

system, including a chromium hydroxide precipitation step, was quoted at $12-15,000 indicating that this must be a small scale operation.

TEER and RUSSELL (1972) described an SO_2 chromate reduction process used to treat wood preserving wastewater in which effluents with 0.23-1.5 mg/l hexavalent chromium were reduced to 0.1 mg/l.

At one plant described by FISCO (1970) to treat hexavalent chromium in plating waste, sulfur dioxide is washed out of the powerhouse stack gas and used for hexavalent chromium reduction. The plant has been in operation since 1959, and when additional reduction is necessary, sodium bisulfite is employed as a supplement.

PATTERSON (1975) points out that the use of SO_2 results in an oxygen demand in the product water unless the effluent is oxygenated by aeration. Required SO_2 dosages of 2.0 lbs. per pound hexavalent Cr has been reported in small industrial applications by the U.S. EPA (1971) and BEEVERS (1972).

AVRUTSKII (1969) described the removal of 140 mg/l Cr(VI) from a plating waste reduced at pH 2.5-2.8 with sodium bisulfite to 0.7-1.0 mg/l Cr(VI). There have been reports of replacing sodium bisulfite with SO_2 because of odors and corrosion hazards experienced with sodium bisulfite. The use of sodium bisulfite to treat a chrome plating waste was reported to yield an effluent hexavalent chromium level of 0.05-0.1 mg/l by METAL FINISH. J. (1971).

The above examples almost all refer to industrial effluents at small flowrates. One treatment plant reduced their initial chrome level from 31.4 mg/l in a cooling tower blowdown of 3600 U.S. gpm to below 0.5 mg/l as reported by LANDY (1971) at pH 2.0. This required the addition of 4.2 pounds of metabisulfite per pound of chromium representing 75% excess over the theoretical dosage required. Elsewhere, PATTERSON (1975) refers to reductive chromate removal from a similar blowdown waste achieving hexavalent chromium levels of 0.025-0.05 ppm.

Three cases, in steel mills where pickle liquor was available for use in the reduction process, were found in which ferrous sulfate reduced hexavalent chromium. These were described by DONOVAN (1970), HEINIKE and VON REICHE (1969), and STONER (1971).

According to GERMAIN, et al. (1968) ferrous sulfate reduction of hexavalent chromium has the advantage of being independent of pH, although BENNETT (1972) found that ferrous sulfate reduction at pH 2-3 proceeds within 30 minutes to a residual Cr(VI) level of 1 mg/l but requires one hour at pH 4-10. The use of ferrous sulfate also yields much larger quantities of sludge than are produced through the use of SO_2 although this is unlikely to be an important factor at the hexavalent chromium levels usually encountered in mineral processing plants.

In 1972, the cost of hexavalent chromium removal from 120 mg/l solution at 100 gpm, including precipitation of $Cr(OH)_3$, came to $1.80/lb. Cr removed.

REMOVAL OF CHROMIUM BY PRECIPITATION

$Fe_2(SO_4)_3$ addition at pH 3.5-4.5 followed by electrocoagulation and Lectroclear flotation has been demonstrated for removal of molybdenum from mine and tailings decant effluents by RAMIREZ (1980) and is the subject of a patent by RAMIREZ and RAMADORAI. According to RAMIREZ (1980), the same process demonstrated, on a laboratory scale, its ability to remove Cr as well. No further details were provided in the chemical abstract CA95(8):67356a.

Co-precipitaton with ferric sulfate when the precipitatable solids load is very small could mean that the cost of clarification of the solution after precipitating the chromium is expensive--ie., clarfier size is determined by liquid flowrate, not the solids loading. In such a case, dissolved air flotation could be considered as a less expensive route than clarification by either Lectroclear flotation or conventional clarification.

No operation was identified that uses these processes for chromate removal from recycle solutions or effluents from mines or mills.

REMOVAL OF CHROMIUM (III) BY PRECIPITATION

Trivalent chromium may be removed by precipitation as the hydroxide by the addition of lime or caustic soda yielding a precipitate which is considered safe for landfill disposal according to PATTERSON (1975).

Treatment Technology for Trivalent Chromium

Effect of pH on solubility of trivalent chromium. [From Parsons courtesy of National Lime Association.]

Precipitation is most effective at pH 8.5-9.5 due to the low solubility of chromic hydroxide in that range, although best removal has been reported in one case by WANG, et al. (1973) at pH 12.2. Because metal-bearing effluents include other metal ions as well as chromium to be removed by precipitation and because the optimum pH for precipitation of different metal hydroxides varies, an average waste stream pH of about 8 is often used in waste treatment from metal finishers according to ZIEVERS, et al. (1968).

Lime is the most commonly used reagent for chromium (III) precipitation although soda ash has also been used. In waste treatment at an IBM plant, hexavalent chromium at 1300 mg/l in one waste stream was converted to trivalent chromium and precipitated with lime to achieve an effluent containing no hexavalent chromium and 0.06 mg/l trivalent chromium according to HANSEN and ZABBEN (1955). A coagulant aid was employed to improve the precipitation-sedimentation removal of chromic hydroxide which had a lot to do with the performance in that 99-99.5% of the suspended solids were removed though the use of the coagulant.

Filtration of precipitated and decanted effluents has significantly improved the quality of a treated effluent from a British metal alloy plant. Precipitation reduced chromium to 1.3-4.6 ppm whereas subsequent filtration reduced it further to 0.3-1.3 mg/l according to PATTERSON (1975). On the other hand, TEER and RUSSELL (1972) described lime precipitation of a dilute wood preserving wastewater containing trivalent chromium up to 2.2 mg/l which yielded an average effluent of 0.02 mg/l in which solids separation was by settling.

In precipitation of metal hydroxides from industrial wastes, large quantities of sludge are produced. Typically, these sludges settle rapidly but do not compact very well and contain only 2-3% solids.

In one case where vacuum filtration was not necessary, sludge from the sedimentation basin was stored for short periods in sludge storage tanks allowing it to compact to 10-12% solids equivalent to that obtainable by vacuum filtration according to HANSEN and ZABBEN (1959).

ANDERSON, et al. (1971) listed several ways of concentrating and disposing of precipitate sludges. Lagooning requires large areas of land and may contaminate ground water unless the lagoon is properly lined. Vacuum and pressure filtration is costly and probably is more applicable to industrial effluent treatment sludges.

REMOVAL OF CR(VI) AND CR(III) BY HDS

BETHLEHEM STEEL COMPANY generates effluents containing chromium in their steelmaking process which must be treated. According to S. T. Herman (1984 Randol

Workshop), the high density sludge (HDS) process has been tested and shown able to remove both Cr(VI) and Cr(III). This process entails recirculating underflow sludges almost quantitatively for mixing with the lime used for pH adjustment ahead of its addition to the effluent stream. More details can be requested from:

BETHLEHEM INTERNATIONAL ENGINEERING CO.
Bethlehem, PA 18016
(215) 694-2424
James Forand
Vice President
Stewart T. Herman

This is a relatively new development, and it was not determined to what levels chromate and chromium ions can be removed using this process, nor where it is applicable. HDS process sludges are often amenable to mixing with pozzolonic materials (e.g., cement, flyash, etc.) to make a stable solid waste disposable in municipal sanitary landfills as it generally passes the EPA toxicity leach test. HDS also has the ability to reduce metal concentrations often to below their theoretical solubilities.

PRECIPITATION - MgO

SCHILLER and KHALAFALLA (1981) applied for a patent for a process which is claimed to be more efficient for the removal of Cd, Cr, Cu, Fe, Mn, Ni, Pb, and Zn from wastewaters. Disadvantages of the prior art processes are largely overcome by the use of a substantial excess of essentially dry powdered reactive MgO as a precipitant in the place of conventional precipitants. The resulting precipitate settles rapidly to a small volume and is not readily redispersed or redissolved. The purified water is claimed to be easily clarified avoiding the need for filtration. The U.S. patent application U.S. 325269 AO dated March 18, 1983, is available from NTIS, Springfield, Virginia, NTIS Order No. PAT-APPL-6-325-269, but it contains almost no useful information. The process belongs to the U.S. Dept. of the Interior and is available under license. Application forms for licensing of the process are available from the NTIS.

HYDROGEN PEROXIDE AND LIME FOR CHROMIUM REMOVAL

BARNES, et al. (date unknown) reported treatment of an industrial effluent containing chromium and phenolic compounds with hydrogen peroxide and lime. Chromium was reduced from 100 mg/l to less than 0.1 mg/l. Chromium originally present as chromate is reduced via a peroxychromium intermediate and precipitates out with the lime sludge. Following this treatment, the effluent is suitable for discharge into biological wastewater treatment plants.

The purpose of peroxide addition is to remove phenol. The process employs a 3:1 peroxide to phenol ratio with 10 mg/l iron and two hours aeration to oxidize the phenol at pH around 4 followed by addition of 6 mg/l lime reduced chromium and phenol concentration in the supernatant. This raised the pH to around 12 during which the chromium was precipitated in the lime sludge.

At the low pH of the oxidaton step of the treatment process, chromium (VI) oxidizes hydrogen peroxide and is thereby reduced to chromium (III). There is evidence that the reaction proceeds via a number of unstable peroxychromium complexes such as $CrO(O_2)_2$, but the mechanism of the process has not been established. Chromium (III) is probably produced by an internal oxidation reduction reaction occurring on decomposition of these complexes.

It is important that any residual peroxide remaining from the initial reaction step is removed prior to the addition of lime since under alkaline conditions hydrogen peroxide will oxidize chromium (III).

$$2Cr^{+++} + 3H_2C_2 + 10\ OH^- = 2CrO_4^{=} + 8H_2O$$

This can be done quite simply by adding 500 mg/l ferrous sulfate which also aids in the following lime treatment process when the pH is increased.

The above process may not be an economical way to treat mine-mill effluents but is reported to provide further understanding of the chemistry of chromium under different conditions.

David Barnes is employed at the School of Civil Engineering, University of New South Wales, Sydney, Australia.

SULFEX PRECIPITATION OF CHROMIUM

Hydroxide precipitation of chromium (III) yields a minimum solubility of about 0.2 mg/l Cr at around pH 7, and the increase in solubility at higher and lower pH values are steep as illustrated graphically below. For example, at pH 10, where zinc has its minimum solubility, the solubility of Cr(III) is around 6 mg/l.

SCOTT (?) showed that with the sulfide precipitation process, it is possible to achieve Cr(III) levels of below 0.05 ppm even though the chromium is, in fact, not precipitated as a sulfide.

Hexavalent chromium is reduced and removed in a single step in the insoluble sulfide precipitation process, the chemistry of which is illustrated by the equation:

$$Na_2CrO_4 + FeS + 4H_2O = \underline{Cr(OH)_3} + \underline{Fe(OH)_3} + NaOH + \underline{S} + 2H_2O$$

In the soluble sulfide process, the sulfide ion is capable of reducing hexavalent chromium as follows:

$$2H_2CrO_4 + 3NaHS + XH_2O = \underline{2Cr(OH)_3} + 3\underline{S} + 3NaOH$$

A U.S. EPA (1980) Summary report claims that a pilot study carried out for the U.S. Navy concluded that the reduction of chromate by a soluble sulfide reagent would be accomplished in the presence of ferrous ions (or some other suitable secondary metal). The ferrous ion acts principally as a calatyst for chromium reduction. Less than stoichiometric doses of iron are required to reduce most of the chromium. Nearly stoichiometric dosages are needed to achieve levels typical of other reduction processes, and no operating systems currently employ this one-step process.

More details of the SULFEX insoluble sulfide process are provided in U.S. EPA (1980), which is available from NTIS, Springfield, Virginia. Results of several sulfide precipitation tests are shown in the table below indicating that hexavalent chromium levels of less than 1 ppb are attainable using sulfide addition in some cases.

Another document describing the sulfide precipitation of heavy metals is EPA-600/2-80-139, 1980.

Although thus far employed only for plating and metal finishing waste effluents, the PERMUTIT-patented Sulfex process and the PERMUTIT sulfide sludge blanket clarifier appear potentially adaptable for large volume throughput applications. The Sulfex process is described in Chapter 25, and more information on the SULFEX process and the licensing arrangements can be requested from:

It is believed that the GE RESEARCH AND DEVELOPMENT LABORATORES have patented a calcium sulfide process for metal precipitation from effluents:

GE RESEARCH AND DEVELOPMENT CENTER
Post Office Box 8
Schenectady, NY 12301
(518) 385-8247.

So far, no sulfide effluent treatment plant has been identified for chromium removal from mine or mill effluents in the mineral processing industries.

ION EXCHANGE

ROSS (1968) claimed that ion exchange is an economical way to recover chromium for reuse from plating operations. Cation exchange can be applied to remove trivalent Cr(III) and anion exchange for chromate and dechromate, ie., Cr(VI).

When anion exchange resin is exhausted, it is regenerated with sodium hydroxide to yield sodium chromate in the eluate. The chromate can either be recovered as chromic and/or reduced to trivalent chromium and precipitated with lime.

In the ion exchange removal of chromium, pH is critical. Below pH 4, the oxidizing power of chromic begins to attack the resin. Above pH 6, the ratio of $CrO_4^{=}/Cr_2O_7^{=}$ in solution increases and, since most anion resins are less selective for dichromate, chromium leakage occurs sooner in this case according to ANDERSON (1974).

Highly basic anion exchange resins preferentially remove chromate at pH 4.5-5 before phosphate or sulfate according to CALMON (1974) who reports an exchange capacity of 1.9 lb. $CrO_4^{=}$ per ft^3 resin.

According to ANDERSON (1974) and CALMON (1974), chromate in recirculating cooling waters can be removed at pH 4.5-5 even in the presence of several hundred or thousand ppm sulfate and chloride. CALMON (1974) claimed that at above 100 mg/l chromate, the recovery of chromate by ion exchange can pay for itself.

One ion exchange treatment process was able to meet a chromate effluent standard of 0.05 mg/l for a metal finishing waste as reported by ROTHSTEIN (1958) which is equivalent to a Cr(VI) concentration of 0.023 mg/l.

RICHARDSON, et al. (1968) reported 0.0-0.90 mg/l effluent chromium levels depending on the period of operation, between exchange resin regenerations. On regeneration, the chromate-rich elute solution was returned to the cooling system with makeup water.

A small plating shop which employs ion exchange was reported in IND. WATER (1973) to have reduced chromate levels to 0.025 mg/l. The concentrated eluate is treated with sodium metabisulfite to reduce chromate followed by neutralization and chromic hydroxide precipitaton.

RICHARD, et al. (1968) describe the use of a NALCO patented ion exchange process for <u>selective</u> removal of Cr(VI) from recirculating cooling water at a UNION CARBIDE-

WASTE CHROMATE DISPOSAL
CHEMICAL CONSUMPTION COMPARISON

Recovery and Reuse (Ion Exchange)

Item	Chemical Usage lb/lb CrO_4
Sulfuric Acid	1.2
Sodium Hydroxide	0.9
Sodium Chloride	1.7
Ion Exchange Resin Replacement	Over 50% of Total

Destruction by Reduction and Precipitation

Sulfuric Acid	0.65
Ferrous Sulfate	10.40
Calcium Hydroxide	3.1

WILMOTH, et al. (1979) found that a dual bed (strong acid-weak base resin combination) ion exchange system was very effective for removal of trace elements including Cr from acid mine drainage.

CHEM-SEPS CHROMIX PROCESS

Chem-Seps Chromix process provides a unique system for recovery of Chrome VI, Chrome III, and Zinc from cooling tower blowdown.

The use of the recovery system allows the preferred corrosion inhibitor chromates to be used and eliminates the pollution problems. The destruct system which is another alternative does not necessarily eliminate pollution. Chrome VI is reduced to Chrome III and precipitated. But today's EPA and other regulatory agencies requirement of 0.05 ppm total chrome are not achievable with the destruct system. Further the destruct systems are expensive to operate. A comparison of chemical consumptions between recovery and destruct is shown below.

	Recovery System	Destruct System
Sulfur Dioxide	None	2 lbs SO_2/lb Cr^{+6} or 1 lb SO_2/lb CrO_4
Sodium Hydroxide	0.75 lbs/lb CrO_4	2.5 lbs/lb Cr^{+6}
Sulfuric Acid	1.00 lbs/lb CrO_4	24.5 lb/lb Cro_4 *

*This consumption is based on 20 ppm of CrO_4 and reduction of pH from 6.0 – 6.5 to 2. The reaction of reduction is best carried out at pH 2.

Typical System

A Chromix system to treat one million gallons per day (700 GPM) of blowdown with a Chromate concentration of 20 ppm would require one Chem-Seps Continuous Unit Model No. 5412 as shown in the flowsheet.

The cooling tower blowdown is pumped to the treatment section of the chromix system where the Chrome VI, Chrome III and Zinc are picked up on Chem-Seps special blend of ion exchange resins. The water leaving this section is essentially chromate-free and may be discharged. After the resin is loaded with the valuable corrosion inhibitors it is moved to the regeneration section. In the regeneration section Sulfuric Acid and Sodium Hydroxide are used to remove the Chrome VI, Chrome III, and Zinc from the resins. The sodium Chromate dichromate and Zinc Sulfate leaving this section may then be recycled to the cooling tower instead of going to sludge as in the destruct system.

OPERATING COST ECONOMIC ANALYSIS

Basis – Chromix System to treat one million gallons per day of cooling tower blowdown containing 20 ppm chromate. Unit model No. 5412 recovers 165 pounds of CrO_4 per day or 4,950 pounds per month. Capital Cost $200,000.

	Cost Per Month
Resin Replacement at $80 per Cu.Ft.	$ 350
Replacement Parts 3 percent of equipment cost	500
Chromate Make Up Cost 1 percent (50 pounds) at $1.75 per pound CrO_4	90
Chemicals and Utilities	
Sulfuric Acid	110
Caustic	180
Power	153
Estimated Labor Cost	
Operation at 1500 per month	1,000
Maintenance at 500 per month	500
TOTAL MONTHLY OPERATING COST	$2,883

Summary

Estimated value of chromate recycled equals $8,662.50 per month.

Payback on capital cost is estimated to be 2.9 years, plus installation cost.

Standard Continuous Units Fully Assembled

A full line of standardized continuous countercurrent ion exchange units have been designed to recycle chromates from 100 gpm up to 2000 gpm in a single unit. Each of these units are shipped fully assembled. A unit arrives on your site ready for feed and service piping connections plus power tie-in to the control panel. Installation and Start-Up cost are low.

Equipment Specifications Available

If you now operate a cooling tower and treat with chromates as corrosion inhibitors or if you do not presently use chromates but would prefer to use them, please contact Chem-Seps. Let us know blowdown rate and chromate level. You will receive a prompt reply including equipment specifications, operating data and an economic analysis that fits your specific cooling tower operation. It could be the start of improved, more economical, pollution-free cooling tower operation for you.

ION EXCHANGE - LIQUID FILLED MEMBRANES

BEND RESEARCH, Oregon, has developed a process for the removal and recovery of hexavalent chromium from plating and metal finishing wastes. They have developed a patented hollow fiber with an inside diameter of around 0.025 inch. The walls of the membrane are "filled" or impregnated with an ion exchanging liquid reagent. Feed solution flows through the filaments and is absorbed into the walls of the filaments and continuously eluted at the outside of the filaments which are submerged in an eluant solution contained in the flow through module. The filaments are packed into modules about 4-6"Ø and three feet long. It was pointed out that these devices are designed to recover usable Cr from plating waste solutions containing approximately 300 mg/l Cr(VI) yielding an effluent with, say, 30 mg/l. The process does not yet appear suitable for removal of Cr(VI) to very low levels needed to meet effluent discharge limits. More information can be requested from:

BEND RESEARCH
64550 Research Road
Bend, OR 97701
(503) 382-4100
Harold K. Lonsdale
President
Dave Kamperman
Manager of Metal Separations

No ion exchange plants recovering or removing chromate from flotation plant effluents were identified during the course of this study. It appears that ion exchange can reach levels below 0.05 mg/l total chromium, but large scale IX plants are expensive and, in the case of this application, could be subject to scaling problems depending on the quality of the effluent or recycled water stream to be treated.

ELECTROCHEMICAL REDUCTION

Reduction of hexavalent chromium to trivalent chromium by cementation with metallic iron or ferrous iron to yield trivalent chromium has been described by PATTERSON (1975).

$$Cr_2O_7^{=} + 3Fe^{o} + 14H^{+} = 2Cr^{3+} + 3Fe^{+2} + 7H_2O$$

$$Cr_2O_7^{=} + 6Fe^{2+} + 14H^{+} = 2Cr^{3+} + 6Fe^{3+} + 7H_2O$$

The reaction requires acidic conditions and is pH dependent. Complete reduction of 100 mg/l Cr^{+6} solution has been reported within eight minutes at pH 2.0 by CHASE (1974).

In one full scale application, hexavalent chromium at 2.5-52.0 mg/l was reduced to 0.01-1.40 mg/l by the cementation process, and average effluent was 0.09 mg/l for an

average chromate reduction of 99.4% according to JOSTER and TAYLOR (1963). The process used scrap iron suspended in a perforated rotating drum through which the wastewater flows at pH 2-3. A similar electrochemical process, but employing an electrical potential and consumable elctrodes, has been reported to achieve chromate reduction to below 0.05 mg/l in cooling tower blowdown by DUFFEY (1974).

EVAPORATIVE RECOVERY

This is not applicable to the very low levels encountered in mine water and metallurgical processing effluents.

ACTIVATED CARBON

Several successes have been reported of chromate removal by activated carbon. In one case, hexavalent chromium levels of 0.09-0.19 mg/l were reduced to 0.04 mg/l Cr(VI) from municipal effluent according to ARGO and CULP (1972). Initial hexavalent chromium levels of 5 mg/l were reduced to 0.006-0.087 mg/l following carbon adsorption according to MARUYAMA, et al. (1972). According to PATTERSON (1975), activated carbon may not be equally effective at higher chromate levels where chromium (VI) reduction efficiencies of 50-99% were experienced.

FAULKNER (undated) described a process whereby activated carbon will rapidly reduce ferric to ferrous iron when a stoichiometric amount of SO_2 is added to a solution and the solution is then passed through a column of activated carbon. A retention time of only a few minutes is needed, and the ferric iron and SO_2 in the effluent are quantitatively reacted. The SO_2 requirement is 0.57 lb. per lb. Fe^{3+}.

FAULKNER (1983) indicates that hexavalent chromium can be reduced in a similar fashion by SO_2 in contact with granular activated carbon. More information can be obtained from:

CALCON CARBON CORPORATION
Post Office Box 1346
Pittsburgh, PA 15230
(412) 777-8000
W. D. Faulkner

SAITO (1979) described bench scale tests in which Cr(VI) was removed from wastewater. He found that removal of Cr(VI) depends on the type of carbon, on pH, and on temperature. The higher the temperature, the lower the residual Cr(VI). The best removal of Cr(VI) was in the pH range 4-6.

Aqueous KOH and sulfuric acid solutions were used to elute chromium from the activated carbon test samples. Residual Cr(VI) showed a tendency to decrease with an increase in the surface area of the carbon used. The data indicates a pH dependence of Cr(VI) adsorption onto carbon but is unclear and does not show evidence of a suitable process for removal of chromium down to very low levels using activated charcoal.

HUANG and BOWERS (1978) investigated the kinetics of Cr(VI) removal by activated carbon. Some of the Cr(VI) is removed by adsorption while the rest (76%) is removed by reduction to Cr(III) which adsorbs less readily onto carbon. By adding 524 mg/l sodium hypochlorite to raise the redox potential or oxidize the carbon surface with 10 normal HNO_3 prior to contact with the solution, the adsorption of hexavalent chromium resulted in 83%-90% total chromium removal after five hours contact time.

There are numerous additional papers on the subject of chromium removal from solutions using activated carbon. Several are listed in HUANG and BOWERS's (1978) paper. These are not listed here because the data and testwork relates more to the levels encountered in plating wastes rather than the very low levels of 0.001-0.100 mg/l that could be expected in flotation plant tailings recycle water and effluents.

DEVOE-HOLBEIN CHROMIUM REMOVAL

DEVOE-HOLBEIN (CANADA), INC. claims to be able to remove metals using a new process which can be tailored to be highly specific, and which they claim reduces metal concentrations to extremely low levels.

DEVOE-HOLBEIN (CANADA), INC. has developed several material "compositions" onto which metals are precipitated. The loaded composition is then recovered and regenerated for reuse in a similar manner to ion exchange resins.

The technology is still in the development stages, and the composition is available in experimental quantities. No cost data is available. However, the company points out that commercial scale operations would be relatively inexpensive once enough of the composition is in use to justify mass production.

More information and details are available from:

DEVOE-HOLBEIN (Canada), INC.
175 Bouchard Blvd.
Dorval, Quebec
Canada H9S-1A9
(514) 636-6042
Dr. Bruce E. Holbein
Dr. L. G. Neirinck

A detailed paper by HOLBEIN, et al. (undated) is included in Chapter 25 on "Removal of Contaminants."

A schematic diagram of the DEVOE-HOLBEIN process is shown overleaf. In addition, the table of data shows that a DEVOE-HOLBEIN composition was able to achieve in excess of 99% chromium removal from two solutions yielding a treated effluent of less than 300 ppb Cr.

HOLBEIN, et al. (undated) showed another example where their composition DH-524 reduced chromium from 694 ppm to less than 0.01 ppm, or a removal efficiency in excess of 99.99%.

DEVOE-HOLBEIN showed three examples of hexavalent chromium containing effluents including one containing calcium and magnesium which would interfere with cation exchange resin removal of Cr(VI). They claim that reduction and precipitation processes for Cr(VI) removal are not quantitative and generate large volumes of sludges that must be disposed of.

The three demonstration solutions were treated using DH-524 composition which reduced Cr(VI) levels to below the detection limit. Capacity of the DH-524 composition for chromium (VI) was claimed to be 20 g Cr(VI) per Kg of composition, and the material was 100% regeneratable resulting in small volumes of concentrated chromium waste which can either be reused in the plating solution at the plant from which it came or sold to the ceramic industry. Spent D-H compositions, after serving their useful lifetime, can also be used as a raw material in the ceramic industry according to the inventors.

DEVOE-HOLBEIN (CANADA), INC. is a research and development company. In order to make their process practical and suitable for use in industry, they have joined forces with the JOHN BROWN COMPANY, an engineering and construction firm, to offer the process to industry. Information is available from:

JOHN BROWN

STARCH XANTHATE REMOVAL OF CHROMIUM

WING, et al. (1974) showed that a starch xanthate with a cationic flocculant PVBTMAC (Polyvinylbenzyltrimethylammoniumchloride) could reduce chromium (III) from 2600 mg/l to 21 mg/l. Two other solutions containing 58 mg/l and 8,250 mg/l Cr were reduced to 1 mg/l and 94 mg/l respectively.

& METAL CONCENTRATION

TABLE 1

TYPICAL EXAMPLES OF METAL CAPTURE FROM SOLUTIONS BY REPRESENTATIVE DEVOE-HOLBEIN COMPOSITIONS

Metal	Composi-tion (A)	Starting (B) concentration	Capture effic. (%)	Residual concentr.
Cadmium	B-1 N-2	10 ppm (Dw) 672 ppm (Tw)	99.99 99.99	0.1 ppb < 67 ppb
Cobalt	B-2 A-1	1.2 ppm (Tw) 364 ppm (Dw)	99.99 99.92	< 20 ppt 292 ppb
Cesium	W-3 P-1	7.97 ppm (Dw) 797 ppm (Dw)	99.99 99.97	< 20 ppt < 250 ppb
Chromium	S-2 W-1	31.2 ppm (Dw) 312 ppm (Dw)	99.04 99.9	< 300 ppb < 300 ppb
Copper	W-3 A-1	38.1 ppm (Dw) 381 ppm (Tw)	99.99 99.99	< 1 ppt 3.8 ppt
Gadolinium	A-1 R-1	31 ppb (Dw) 943 ppm (Dw)	99.9 99.9	< 20 ppt 0.7 ppb
Iron	F-1 F-2	58 ppb (Dw) 34 ppm (Sw)	99.99 99	58 ppt 34 ppb
Lead	A-2 P-1	42 ppm (Dw) 1243 ppm (Dw)	99.99 99.92	42 ppb < 940 ppb
Mercury	W-1 Y-2	12.0 ppm (Dw) 120 ppm (Dw)	99.96 > 99.9	4.8 ppb 1.2 ppb
Nickel	G-1 P-1	88 ppb (Tw) 352 ppm (Dw)	99.99 99.94	1.3 ppt < 200 ppb
Silver	W-3 Z-1	10.8 ppm (Dw) 847 ppm (Dw)	99.99 99.87	900 ppt < 870 ppb
Thorium	B-1	139 ppm (Tw)	99.99	139 ppt
Uranium	B-1 F-1	24 ppb (Tw) 24 ppb (Sw)	99.99 99.98	24 ppt 1.7 ppb
Zinc	H-3 W-3	6.8 ppm (Dw) 943 ppm (Dw)	> 99.3 > 99.9	< 20 ppt 0.7 ppb

Low concentrations were measured by counting using radioactive metal tracers.

A. Measured with 4 gms. column of composition: capacities vary with composition but range typically between 3 mg. to 25 mg. metal per gram of compound.

B. Test metal contained in demineralized water (DM), sea water (SW), Montreal tap water, St. Lawrence Seaway (TW) or photographic fix-bleach (PF).

C. Concentrations given as parts metal by weight per parts water by volume (eg. 1 ppt = 1 microgram/litre).

TABLE 7

Recovery of Cr from Various Waste Waters With DH-524

Type of Waste Water	Influent Cr VI ppm	Treated Effluent Cr VI ppm [a]	Cr Removal Efficiency %	Capacity mg CrVI per kilogram Composition	Regeneration Efficiency [c]
1. Boiler Blow Down	694.3	N.D. [b]	>99.99	≈20,000	100%
2. Plating Waste precipitator effluent	3.8	N.D.	>99.99	≈20,000	100%
3. Cooling Tower Bleed	7.6	N.D.	>99.99	≈20,000	100%

[a] Flow rate of 20 bed volumes per hour in a fixed bed of DH 524

[b] N.D. not detectable by atomic absorption spectrophotometry

[c] 100% of bound Cr displaced in approximately 3 bed volumes of regenerant. Fully regenerable over 15 cycles of use so far tested.

	Influent Cr(III) mg/l	Effluent Cr(III) mg/l
Solution A	2600	21
Solution B	58	1
Solution C	8250	94

The above work demonstrating regenerable insoluble starch xanthate was carried out by the U.S. Dept. of Agriculture. An experimental resin containing starch xanthate was prepared by Dow Chemical Co., Midland, Michigan, in 1974. The work was performed by:

CEREAL PRODUCTS LABORATORY
Northern Regional Research Laboratory
Agricultural Research Service
U.S. Department of Agriculture
Peoria, IL
Robert E. Wing

Although demonstrated on a laboratory scale in, 1974 RANDOL INTERNATIONAL LTD. did not encounter any commercial scale applications of this technology--neither in the mining and mineral processing industry nor in industrial effluent treatment. This is not a poor reflection on its performance, however, but rather a reflection on the receptiveness of industry to try new technology. Perhaps chromium adsorbs as $Cr(OH)_3$.

It is interesting that chromium, which does not form an insoluble sulfide precipitate, can still be removed to very low levels using an insoluble starch xanthate which has active groups containing sulfide.

Advantages of the processes claimed by WING, et al. (1974) are:

1) The composition is easily regenerated using a mild acid which elutes the metal.

2) The volume of sludge generated is small compared with lime treatment.

3) The non-gelatinous sludge settles rapidly and more quantitatively than most metal precipitates.

4) Suspended solids need not be removed before treatment with insoluble starch xanthates.

5) The starch xanthate method is effective over a pH range 3-11.

6) Only very slight reagent excess is needed to achieve minimum levels of metal in solution.

Very recent development work along the same lines was identified in 1984-85. Insoluble starch xanthate and carbamate materials as well as the knowhow and equipment in which to use them are available from:

REVERSE OSMOSIS

R.O. has been reported to have application in hexavalent chromium removal although experience with the process is limited. Improved efficiency seems possible when the solution is first neutralized.

At pH 2.6, a high selectivity cellulose acetate membrane yielded 92.6% with 98.6% rejection at pH 7.6 according to CRUVER (1973).

It is not for one minute proposed that a relatively expensive R.O. plant be installed for hexavalent chromium removal, but if such a plant is installed in any case for any one of several other reasons, then it is interesting to note that it may be possible to benefit from its Cr(VI) removal ability as an added advantage.

In this respect, it is of interest to note that at the pilot plant installed at the RAND MINES ERPM Hercules Shaft on the Witwatersrand, to demonstrate seeded slurry reverse osmosis, total chromium was reduced from 0.08 mg/l to less than the 0.02 mg/l Cr detection limit.

WILMOTH, et al. (1979) found that reverse osmosis was effective in removing mg/l levels of trace elements from acid mine drainage including Cr. It was not determined what type of reverse osmosis system was used for the test except that this work predates seeded slurry developments in R.O. applications.

BIOLOGICAL POLISHING OF EFFLUENTS

Natural marshes may conceivably be developed for effective use in polishing mine and mill tailings effluents for metal removal to very low levels. Biological polishing of effluents occurs in the New Missouri lead belt and at ST. JOE MINERALS operations at Edwards, New York. However, data is not available for chromium removal. Marshes offer the potential for synergistic metal removing processes involving aqueous plants, algae, and bacteria, including generation of sulfides in the anaerobic zone. It is not known what

effect the biological system would have on chromium levels or the effect of accumulated chromium precipitates on the marsh itself. Conceivably, if marsh ecologies remove hexavalent chromium, water reclaimed for recycle could be treated in the bog prior to recycle to the plant to avoid metallurgical interferences by residual Cr(VI).

Mr. Hans Von Michaelis
Metallurgical Consultant
Randol International Limited
21578 Mountsfield Drive
Golden, CO 80401

Dear Mr. Von Michaelis,

Attached is the Diamond Shamrock Technical Bulletin reviewing treatment systems for chromium bearing wastes. I hope this helps your understanding of what is required for treatment of water containing low levels of chromium.

If you should have any further questions, feel free to call.

Sincerely,

DIAMOND SHAMROCK CHEMICALS COMPANY

Roy Yelverton

Technical Bulletin

Introduction

Users of chromium chemicals are, or will be in the near future, required to perform some degree of treatment of chromium bearing effluents before they are discharged. Because of the reported toxic nature of chromium chemicals, specifically chromic acid, chromates, and dichromates (hexavalent compounds), it is essential that these materials do not enter receiving bodies indiscriminately.

Fortunately the technology of treating chromium wastes has been proven and used successfully for several years. So many treatment systems for chromium are commercially available that the problem is choice of a particular system. This bulletin presents some fundamental information relating to commercially available systems.

Toxicity

The toxicity of chromium chemicals has not been well defined and reports on human toxicity are limited. The U.S. Dispensatory, for example characterizes potassium dichromate as a violent irritative and corrosive poison, which can be fatal.[1] On the other hand, consumption of hexavalent chromium in water up to 25 ppm (25 mg/1) has been reported without harmful effects.[2]

McKee and Wolf[3] have concluded that water containing as much as 5 ppm (5 mg/1) of hexavalent chromium could be consumed without deleterious physiological effects. Hexavalent salts will impart a yellow color to water at a very low concentration, 1.5 ppm, and is easily detected in water solutions. This same concentration is near the taste threshold. For domestic water supplies the U.S. Public Health Service set a mandatory limit, in 1946, of 0.05 ppm hexavalent chromium. The World Health Organization (WHO) International Drinking Water Standards prescribed the 0.05 ppm limit. The .05 ppm limit was the lower limit of detectability at that time.

Generally salts of trivalent chromium are not considered to be physiologically harmful.[4] Administered orally, the chromium salts are not retained by the body, but are rapidly and completely eliminated.[5] There is no evidence that trivalent chromium compounds have any toxic effects.[6] In fact, Mertz[7] has concluded that chromium, as Cr^{+3}, appears to be an essential trace metal in mammalian metabolism. The less toxic nature of trivalent chromium was reflected in the 1962 Drinking Water Standards set by the U.S. Department of health, Education, and Welfare which placed a limit of 1.0 ppm trivalent chromium. The 0.05 limit was retained on hexavalent chromium.

Restrictions

Specific restrictions for discharge of chromium bearing wastes vary substantially according to the point of discharge and the nature of the industrial process which generates the waste chromium. The regulatory agency for any particular plant may be a Federal, a State, or local agency, or perhaps a combination of the three.

The United States Environmental Protection Agency (EPA) has been charged with the responsibility of developing effluent limitation guidelines for several industrial operations, as well as setting up a permit system. An initial task has been to survey specific industries to determine, in the case of heavy metals (chromium included), the best practicable control technology currently available to remove all, but small amounts, of heavy metals from the effluent of existing point sources.[8,9] The EPA has concluded that chemical treatment is an acceptable method and has prescribed the quantities or pounds of chromium (hexavalent, trivalent and total) per day which may be discharged. The number is based upon some unit of production and therefore is different depending upon the process. The initial guidelines are for those sources which discharge into navigable waters; however, additional guidelines for new point sources will differ from existing point sources to reflect new technology. The EPA also prescribes guidelines for new point sources discharging into municipal sewage treatment plants, as well as navigable waters.

Discharge of chromium wastes into municipal sewage treatment plants is a different problem as some plants have a capacity to assimilate chromium wastes and others do not. The ability of a municipal plant to receive chromium wastes dependds upon the treatment plant type, the treatment plant capacity and loading, the dilution, the other types of industries discharging into the plant, etc. In some large metropolitan areas chromium has been accepted without treatment, while in other areas some degree of treatment is required. The local regulatory agency generally prescribes the limitation; however, EPA has prepared preliminary pre treatment standards which may influence the treatment requirements.[10]

Information concerning specific requirements should be obtained from State and/or Local Offices, of the EPA. A listing of EPA Regional Offices is located in Appendix I.

Sources of Chromium Pollution

Chromium chemicals have applications in a number of industrial operations including plating and metal finishing, pigments, leather tanning, corrosion control agents, textile dyeing and mordants, wood preservation, photography, catalysts, etc. All of these industrial applications present a potential source of waste material which may require treatment. The extent of treatment required depends upon the specific industrial process used and the particular chromium chemical which is to be treated (hexavalent or trivalent chromium)

Treatment systems for chromium bearing wastes have been commercially developed and include both destructive and recovery systems. Although the systems have been developed primarily for the metal finishing industry, the application is essentially the same for any source of chromium waste. Most processing applications employing hexavalent chromium require rather concentrated chromium solutions. After processing, some sort of a rinising or washing operation is performed whereby a dilute chromium waste is generated. The optimum or most efficient system of rinsing is that which employs counter-current or cascading rinse operations. Use of counter-current rinse operations will reduce water usage, treatment costs and equipment size.

Application

In order to determine the application of a particular waste treatment system for chromium, it is essential to understand some basic chromium chemistry. Specifically, it is necessary to distinguish between hexavalent chromium and trivalent chromium since differences in the chemical properties of the two form the basis of design of destructive and recovery systems.

Hexavalent chromium (Cr^{+6}) is the highest oxidation state of chromium. The common chromium chemicals which are composed of hexavalent chromium are chromic acid (or chromium trioxide) CrO_3; the bichromates, $Cr_2O_7^{=}$ and chromates, $CrO_4^{=}$. The basic building block of all hexavalent chromium chemicals is sodium bichromate dihydrate, $Na_2Cr_2O_7 \cdot 2H_2O$, or technically sodium dichromate, dihydrate. All other common hexavalent chromium chemicals; chromic acid, sodium chromate, and potassium bichromate, are derived from sodium bichromate. Solutions of chromic acid, sodium bichromate, potassium bichromate and sodium chromate, contain hexavalent chromium, which, in dilute solution, is essentially the same regardless of the source. Chemical differences are more pronouned in concentrated solution; for example, concentrated chromic acid solutions have a low pH (2.0 or less) and are very strong oxidizing agents. Sodium bichromate solutions nominally have a pH of 4.0 and are not as strong oxidizers as chromic acid unless the pH is lowered with some mineral acid. Sodium chromate solutions have a nominal pH of 8.6 and show the least oxidizing characteristics. All of the common commercial hexavalent salts are quite soluble at any pH, consequently the chromium cannot be precipitated out of solution as the hydroxide without conversion to trivalent chromium. The process is described later.

Trivalent chromium (Cr^{+3}) is a lower oxidation state of chromium. Trivalent compounds do not exhibit the strong oxidizing characteristics of hexavalent and are soluble only at low or very high pH levels. At a pH of 8.6 trivalent chromium is essentially insoluble.

Trivalent chromium chemicals such as chromic chloride, chromic acetate, and chrome alums are trivalent salts. These salts are soluble since water solutions are acidic. Treatment of waste from these sources is a precipitation of the chromium salts by a simple pH adjustment. Chromic oxide, or chrome green, is obtained by reduction of sodium bichromate and precipitation of the hydroxide $Cr(OH)_3$. Upon dyring Cr_2O_3, chromic oxide, is obtained. This material is highly insoluble and can reaidly be treated by mechanical separation.

Most commercial systems available for treatment of hexavalent chromium wastes are designed to handle rather dilute solutions. Disposal of more concentrated solutions, particularly contaminated processing solutions, will present problems. In these instances, the concentrated material must be slowly introduced. from storage, into the rinse water stream for dilution before treatment.

Process Selection

Process selection and design can be very complex for a number of reasons. Since every operation is different, a good engineering study should be made. This can often be accomplished "in house"; however, employing reputable consulting engineers, or relying upon reputable equipment vendors is highly recommended.

Basically a decision must be made between a destructive system and a recovery system. In order to make such a choice, as well as design the equipment, a number of variables must be considered. Some of these are: The volume (flow rates) and concentration to be treated; chemical costs; energy costs; labor and equipment costs; operating and maintenance costs; the amount and value of the chromium which could be recovered; regulations on effluent quality, etc.

Generally, justification of a recovery system requires that large quantities of hexavalent chromium can be recovered in a usable form, as well as recovery and reuse of water. The capital expenditure for recovery systems is substantially higher than destructive systems. Recovery systems using evaporative methods sometimes require expensive corrosion resistant equipment. Additionally some provision, usually ion exchange, is required to purify the chromium processing solution since impurities concentrate as well as the chemical being recovered. Only certain types of ion exchange resins are useful for purification since the organic resins tend to be oxidized by the hexavalent chromium; however, suitable resins are commercially available. The practical life of these will depend upon the specific application.

Chemical Treatment

The chemical treatment of hexavalent chromium wastes is a two-step process. The first treatment insures the reduction of the hexavalent chromium to trivalent chromium. The second step brings about the removal of the trivalent chromium from solution by precipitation of highly insoluble chromic hydroxide.

Reduction

The most common reducing agents used in the first step are sulfur dioxide, or its salts - sodium meta bisulfite, sodium bisulfite, or sodium sulfite. Ferrous ion, either the chloride or sulfate is an exceptionally good reducing agent which may be used in place of SO_2 or the sulfites. The distinct advantages of ferrous salts are: They are inexpensive, and readily available; there is no need for ventilation of the treatment tank; and the pH or the reaction is not as critical as it is with the sulfite or sulfur dioxide reducing agents.

Sulfur dioxide, SO_2, is the most commonly used reducing agent for hexavalent chromium. The material is supplied as a liquid in various size pressurized cylinders. Application is brought about using a sulfonator (the preferred method), a gas diffuser, or as a water solution.

Addition of SO_2 to water results in the formation of sulfurous acid, H_2SO_3, which is the active reducing agent. Usually the sulfur dioxide is not efficiently converted to sulfurous acid and some of the SO_2 escapes the solution. Because of the toxic and corrosive nature of the SO_2, it is necessary to provide exhaust facilities over the treatment tank.

The alkaline salts of sulfur dioxide-sodium bisulfite, $NaHSO_3$; its anhydride sodium metabisulfite, $Na_2S_2O_5$; or sodium sulfite, Na_2SO_3; find use as reducing agents for hexavalent chromium. These materials are supplied in a dry crystalline form and offer some advantage over SO_2 in ease of handling. Their action as a reducing agent is identical to that of SO_2. These salts, in an acidic solution, generate SO_2 which combines with water to form sulfurous acid. With these salts it is also necessary to provide ventilation since excess SO_2 may be released from solution.

The net result in the reduction reaction is the same as SO_2 at any given pH once the sulfurous acid is generated. The quantities of reducing agent, sulfuric acid, and alkali for precipitation are tabulated in Table 1 for each of the reducing agents.

The quantities tabulated are the exact stoichiometric quantities based on the equations written for chromic acid in water (H_2CrO_4) below. The requirement for sulfuric acid will vary somewhat if the material being treated is a dichromate or a chromate, or there is some alkalinity in the waste water.

(1) Sulphur Dioxide - SO_2
$3\,SO_2 + 2H_2CrO_4 \rightarrow Cr_2(SO_4)_3 + 2H_2O$

(2) Sodium Bisulfite
$6NaHSO_3 + 4H_2CrO_4 + 3H_2SO_4 \rightarrow 2Cr_2(SO_4)_3 + 3Na_2SO_4 + 10H_2O$

(3) Metabisulfite - $Na_2S_2O_5$
$3Na_2S_2O_5 + 4H_2CrO_4 + 3H_2SO_4 \rightarrow 2Cr_2(SO_4)_3 + 3Na_2SO_4 + 7H_2O$

(4) Sodium Sulfite - Na_2SO_3
$3Na_2SO_3 + 2H_2CrO_4 + 3H_2SO_4 \rightarrow Cr_2(SO_4)_3 + 3Na_2SO_4 + 5H_2O$

Liquid SO_2 is the most economical of the sulfite reducing agents. The next most economical sulfite salt is sodium metabisulfite which is often referred to as anhydrous sodium bisulfite. The anhydrous material is the normal commercial bisulfite salt as it is less hydroscopic and more stable than sodium bisulfite. On an SO_2 basis sodium metabisulfite is slightly less expensive than sodium sulfite.

From the equations it will be noted that only sulfur dioxide, because of the formation of H_2SO_3, generates sufficient acid to lower the pH of the solution to be treated to approximately 5. With stoichiometric quantities, SO_2 will reduce hexavalent chromium under pH conditions as high as 5.5; however, from Figure 1, which shows the effect of the reaction pH on the rate, a lower pH is required to achieve the optimum rate and minimize the retention time. A pH range of 2 to 3 will permit complete reaction without a large excess of SO_2 and excessive retention time. Although not shown in the table, acid, usually sulfuric, is required to carry out an efficient reduction reaction.

Figure 1 REDUCTION RATE OF HEXAVALENT CHROMIUM WITH SO_2 AT VARIOUS pH LEVELS

A good alternative to sulphur compounds for the reduction process is divalent iron, either ferrous sulfate, $FeSO_4 \cdot 7H_2O$; or ferrous chloride, $FeCl_2$. Ferrous sulfate (copperas) is readily available as a dry crystalline material at a relatively low cost. In some locations spent pickle liquor (hydrochloric or sulfuric acid which has been used to descale or remove rust from steel) is available as a waste material and may be obtained readily at a lower cost than the commercial salts. Spent pickle liquor also contains some free acid thereby reducing the acid requirement when ferrous salts are used.

The reaction which normally is written to illustrate the reduction of chromium with ferrous sulfate is:

$$6\ FeSO_4 \cdot 7H_2O + 2H_2CrO_4\ 6H_2SO_4 \rightarrow Cr_2(SO_4)_3 + 3Fe_2(SO_4)_3 + 5OH_2O$$

Thus, the stoichiometry indicates that 16 pounds of ferrous sulfate are required to reduce each pound of chromium, on a Cr basis.

Although the equation shows a requirement for acid, it is not necessary to carry out the reduction since the reduction reaction will proceed in neutral solutions according to the equation:

$$H_2CrO_4 + 8H_2O + 3FeSO_4 \rightarrow Cr(OH)_3 \downarrow + Fe(OH)_3 \downarrow + 3H_2SO_4$$

Table 1: CHEMICAL REQUIREMENTS FOR CHROMIUM TREATMENT

Reducing Agents

	Sulfur Dioxide 100% SO_2	Sodium Bisulfite 97.5% $NaHSO_3$	Sodium Metabisulfite 97.5% $Na_2S_2O_5$	Sodium Sulfite 97.5% Na_2SO_3	Ferrous Sulfate 100% $FeSO_4 \cdot 7H_2O$	Ferrous Chloride 100% $FeCl_2$
Pounds of Reducing Agent Required[1]	1.85	3.10	2.82	3.64	16.0	7.28
Acid 66° Be H_2SO_4 (93%)	0.0[2]	1.61	1.56	3.12	0.0	0.0
Alkali -						
NaOH (100%)	2.31	3.53	3.49	4.67	Variable[3]	Variable[3]
Na_2CO_3 (100%)	3.06	4.68	4.63	6.20		
$Ca(OH)_2$ (100%)	2.14	3.27	3.23	4.33		
Sludge Generated	1.98	1.98	1.98	1.98	8.12	8.12

[1] All table values are the pounds required per pound of chromium as Cr; to convert to pounds required per pound of CrO_3 multiply the table values by 0.52; and to convert to pounds required per pound of $Na_2Cr_2O_7 \cdot 2H_2O$ multiply the table values by 0.349.

[2] In practice sulfuric acid is required to efficiently reduce the chromium.

[3] Alkali requirements depend upon the pH of the chromium solution to be treated.

Similar equations may be written for ferrous chloride. This reaction is only slightly less faborable thermodynamically than the reaction which takes place under acidic conditions; consequently, the acid requirements are of no importance. The ferrous salts are excellent reducing agents in both acid and neutral solutions.[11]

In practice most chromium bearing solutions will be acidic, except for the chromate solutions. Additionally ferrous sulfate, when hydrolized, will provide hydrogen ions which will lower the pH of the solution being treated. Under these conditions the only alkali required would be amount necessary to precipitate the reduced chromium and the iron. Under some conditions it is possible that no alkali is required after a ferrous reduction. This would require that the solution to be treated is alkaline initially and that the resultant pH of the solution after the addition of the ferrous salt is neutral. Usually one would expect the treated solution to be somewhat acidic requiring a small amount of alkali to precipitate the reduced chromium and the iron.

The obvious disadvantage to the ferrous salts is the formation of sludge from the precipitation of ferric oxide. Where separation by settling is employed, the use of ferrous salts may not be a disadvantage since the ferric hydroxide which is formed is an excellent flocculating agent which will hasten the settling of the precipitated chromic hydroxide.[12]

Neutralization and Precipitation

The completely reduced chromium is prepared for separation from the effluent stream by precipitation with alkali. Lime, soda ash, or caustic soda are suitable alkalies for precipitation. Care must be exercised in maintaining the proper pH range for precipitation since trivalent chromium is amphoteric (soluble at both low and high pH levels). Fortunately the optimum pH range for quantitative precipitation, namely 7.5 to 9.0, is essentially within the pH range of acceptance for discharge into most receiving bodies, which generally is 6.0 to 8.5. Figure 2 shows the relationship between the solubility of chromic hydroxide and pH.

Figure 2: Relationship between the Solubility of $Cr(OH)_3$ and pH

The neutralization reactions are described below:

Alkali	
Caustic Soda NaOH	$Cr_2(SO_4)_3 + 6NaOH \rightarrow 2Cr(OH)_3 + 3Na_2SO_4$
Soda Ash Na_2CO_3	$Cr_2(SO_4)_3 + 3Na_2CO_3 + 3H_2O \rightarrow 2Cr(OH)_3 + 3Na_2SO_4 + 3CO_2$
Hydrated Lime	$Cr_2(SO_4)_3 + 3Ca(OH)_2 \rightarrow 2Cr(OH)_3 + 3CaSO_4$

From these reactions the stoichiometry is determined and summarized in Table I.

Sludge Removal

The nature and the amount of sludge formed during the treatment are determined by the reducing agent and the alkali used to precipitate the reduced chromium. Table I gives a comparison of the quantities of sludge resulting for the various reducing agents.

Substantially more sludge is generated using ferrous salts as a reducing agent since ferric hydroxide is precipitated from the solution with the chromic hydroxide. If lime is used to precipitate the metals another potential source of sludge is the calcium sulfate by-product from the neutralization reaction. The concentration of calcium sulfate must exceed 3 grams per liter before it will precipitate.

Once the pH has been properly adjusted, the chromium is quantitatively precipitated and may be removed from the effluent stream. The precipitated trivalent chromium is one of the least soluble of the

hydroxides of heavy metals having a solubility product of 6.7×10^{-31}, and is considered insoluble, and inert. The reduced chromium is not, under ordinary conditions, readily reoxidized.

Separation

Since precipitated chromic hydroxide is a gelatinous material, removal and dewatering is not always simple. The surest method of separation is pressure leaf filtration using a filter aid.

Clarifiers, or settling basins (if land is available), are suitable methods of separation. A plain settling clarifier may be unsuitable because the settling rate of the precipitated chromium is slow. This problem may be overcome by:

(1) Using special flocculating agents, or polyelectrolytes.

(2) Using a slant tube clarifier.

(3) Using lime, $Ca(OH)_2$, for neutralization permits slightly faster settling.

(4) Using a ferrous salt for the reduction reaction, which upon neutralization, precipitates ferric hydroxide, a flocculating agent.

With clarifiers or settling basins it is difficult to dewater the sludge. Normally the solids concentration of the sludge from these operations runs between 2% to 15%. Using pre-coat vacuum filtration of the underflow from a clarifier may permit dewatering to a solids concentration of over 20%. The same may be achieved with pre-coat pressure leaf filtration. The advantage of dewatering to this extent is to reduce the volume of the sludge and the handling problems.

In some locations very low limitations on suspended solids concentration may be imposed. In such instances, filtration of the clarifier overflow may be required. This normally is accomplished by means of a sand filter.

One of the most straightforward methods of separation is centrifuging. Centrifuges are available which will continuously discharge partially dewatered sludge from chromium treatment systems. These may be used either to separate the sludge from the underflow of a clarifier, or to separate the sludge from the underflow of a simple settling tank which concentrates the sludge.

The options for separation systems are many since numerous variables enter into design. The choice will be dictated largely by the quality of effluent required. Once this is determined the choice of system can be developed.

Commercial Systems of Chemical Treatment

Equipment for waste treatment systems is readily available commercially. Systems which are sold commercially are both batch treatment and continuous flow-through systems. The equipment is supplied either as separate units for each step in a building block system, or as fully instrumented, automatic, pre-packaged units.

Batch Systems

Batch systems have the distinct advantage over continuous systems since there is complete assurance that the hexavalent chromium is completely treated and removed. This can be determined by an extremely sensitive simple spot test. A simple analytical method is described in Appendix II.

A typical batch system, shown in Figure 3, consists of an agitated treatment tank followed by another tank used as a holding tank while treatment takes place in the first tank. Although the system shown in Figure 3 is somewhat automated with pH probes, metering pumps, and an ORP (oxidation reduction potential) meter, a manual system using simple checks for pH and completeness of reduction as well as a manual addition of chemicals is entirely suitable.

Figure 3 **AUTOMATED BATCH CHROMIUM TREATMENT SYSTEM**

Continuous Systems

A typical continuous flow-through system is shown schematically in Figure 4.

Figure 4 **CONTINUOUS FLOW THROUGH TREATMENT SYSTEM**

The advantage of an automated system is that the reduction-oxidation control is related directly to the concentration of hexavalent chromium. Thus, the reducing agent controller feeds the proper amount of chemical regardless of the concentration of hexavalent chromium. The system cannot adjust for large, rapid changes in concentration, consequently a holding, or equalization tank may be required. A properly sized reaction tank would eliminate problems resulting from rapid fluctuations in concentration.

Savings in chemical costs should be realized by elimination of excessive chemical use and perhaps some labor costs may be realized as opposed to a manual batch operation.

The Integrated System

A unique approach to the destructive chromium system is the integrated waste treatment method.[13] The system was developed specifically for metal finishing wastes, but could possibly be applied to any source of dilute chromium waste rinse. The system uses the final rinse tank, in a series of rinses, as a reduction tank. A solution of the reducing agent is the final rinsing material. The reducing solution is continuously recirculated to the final rinse tank from a reservoir tank.

One advantage of the system is that the concentration of reducing agent in the rinse is much greater than the chromium being treated. This asures complete reduction of the hexavalent chromium and accelerates the reaction without requiring acid. The reduced chromium is returned to the reducing reservoir tank which is sized to provide retention time for settling and separation of the precipitated chromium. Additional chemicals are added, at the rate of their consumption, to the clarified overflow which is recirculated. Other apparent advantages are: (1) Reduction chemicals are not wasted since excess chemicals are recycled; (2) rinse water is recycled continuously therby reducing the amount of water usage; and (3) the need for close chemical control is eliminated.

Electrolytic

A rather unique development which has found commercial application for reduction of chromium is an electrolytic process.[14]

In this cell, a dilute solution of hexavalent chromium is reduced electrolytically at the cathode. The cell contains a bed of semi-conductive particles between the electrodes which permit the passage of direct current at a rather low voltage (1-15 volts) and provides an infinite number of cathode sites where the reduction occurs.

The system reportedly operates with a high efficiency and results in a low power cost; lower than the chemical costs for the chemical destruction process.

Dilute chromium containing wastes are collected in an equalization tank. The pH is lowered and the solution is pumped to the cell through a filter to remove suspended solids. The solution of reduced chromium discharges from the cell. Subsequently, the pH is adjusted to precipitate the reduced chromium which is removed by settling, centrifuging or filtering.

Evaporative Recovery

For recovery of chromium for reuse, evaporative methods have proven successful and are used commercially. The evaporative process can be as simple as heating coils in a tank to evaporate water, or as complex as vacuum systems. The evaporator functions to both concentrate the chromium solution and return high quality water for rinsing operations. The use of an evaporator requires conservation of water for rinsing operations. The use of an evaporator requires conservation of water to justify the operational costs; thus, counter-current rinsing operations are required. Several schemes of operation are possible:

(1) **Closed Loop** - The closed loop system is described in Figure 5.

Figure 5 **CLOSED LOOP EVAPORATIVE RECOVERY**

In this system the flow from the first counter-current rinse operation is directed to the evaporator, usually from a holding tank. The concentrate from the evaporator is returned to a holding tank which replenishes the chromium in the processing tank. The condensate (distilled water) is returned to the final rinse tank. It is obvious that no external rinse water is added, except for that lost by atmospheric evaporation; nor are any of the process chemicals lost other than those consumed. All of the chemicals normally lost by drag-out are recovered. To achieve this balance the evaporative capacity must be designed so as to equal the flow of water required for effective rinsing. This usually is not the case therefore, the ideal situation may only be closely approximated. Additionally, all salts added to, or generated by, the processing and rinsing operations are concentrated in the evaporator. These materials may be objectionable in the chromium processing solution. This may be overcome by consideration of the optimized system described in (3) on page 13.

(2) **Open Loop** - This arrangement, shown in Figure 6, is a variation of the closed loop which provides partial recovery.

Figure 6 **OPEN LOOP EVAPORATIVE RECOVERY**

The open loop system becomes a necessity if it is not possible to install a sufficient number of counter-current rinse tanks. For this system a portion of the solution from the final rinse operation is not recirculated through the evaporator. This portion is collected and treated by chemical means. With two counter-current rinse tanks after the process solution approximately 96% to 99% recovery may be possible. Provision must be made for treatment of the excess waste.

(3) **Optimized Closed Loop** - The optimized system makes provision to remove impurities which concentrate in the system. Figure 7 is a schematic of the process.

Figure 7 **OPTIMIZED EVAPORATIVE RECOVERY**

The diagram shows a closed loop system to which has been added purification equipment. For hexavalent chromium processing solutions, a cation exchanger is placed in the process between the first rinse station and the evaporator. This exchanger's function is to remove the cationic materials, usually metal contamination such as iron, copper, nickel, etc. Trivalent chromium is also removed selectively from the hexavalent chromium.

A demineralizer is added to the overflow from the final rinse tank. Any mineral contamination is removed by this bed and deionized water is recirculated to the third rinse tank with distilled water from the evaporator.

Provision may also be made to recirculate the process solution, if it is operated at an elevated temperature, through the evaporator. Thus, the process solution may be heated to a specific temperature and maintained at that temperature by the evaporator. Evaporation costs are reduced by not overconcentrating the rinse water. The evaporator will also provide level control for the process solution.

Provison must be made to treat the wastes regenerated from the ion exchanger.

Ion Exchange

Ion exchange is another commercial process which is used for concentration of chromium wastes. In some cases it is possible to recover the hexavalent chromium solution. The flow diagram in Figure 8 describes a typical system.

Dilute chromium waste, from the first rinse in a series of counter flow rinses or from some other source, is pumped through a cation exchanger to remove metals and then through an anion resin. Specific anion resins have the ability to exchange chromates, thus concentrating them on the resin. When the maximum amount of hexavalent chromium has been exchanged, the resin is regenerated with a fairly concentrated solution of sodium hydroxide. A solution of sodium chromate is recovered which may or may not be usable. If it cannot be used as the chromate, the chromium is readily treatable using the conventional destructive system. Savings are realized by the recovery and reuse of water.

An alternative to destroying the eluted sodium chromate is to pass the eluted sodium chromate through a different cation exchanger resin. Concentrated chromic acid is eluted from the bed with sulfuric acid. The chromic acid may be recovered in concentrations up to 6%. If used at a higher concentration evaporation would be required.

Figure 8 **ION EXCHANGE TREATMENT**

Other Methods

A number of methods have been demonstrated as effective, at least on a laboratory or pilot scale, for chromium waste treatment. Two such processes, namely reverse osmosis and carbon absorption, have the distinct possibility of commercial application.

Reverse Osmosis

This process has been the object of intense development. Basically the process allows separation of a salt from water by applying pressure or energy difference between two solutions of different concentrations separated by a suitable membrane. Thus, the permeate, or the material forced through the membrane, is purified water and the concentrated chromium solution, the concentrate, remains on the high pressure side of the membrane. The reverse osmosis unit may be used in place of either the evaporator or the ion exchange unit in a recovery system. Chromium, in the concentrate, may be recovered and reused, and the purified water, the permeate, may be recycled.

The most commonly used membrane for the process is a cellulose acetate. The membrane cell is operated at high pressure (400-800 psig), below 100°F, and over a pH range of 2.5 to 7.0.

Problems which may arise are fouling of the membrane, by compaction or attack of the membrane by the chromium solution. New developments in membrane materials may solve these problems.

Carbon Adsorption

As a result of a study sponsored by the Metal Finishers' Foundation, a pilot plant operation, based on carbon adsorption, has proved rather successful and could find commercial application.[15] The system is able to remove chromium from dilute rinse solution and is used in both open and closed loop schemes.

Problems with the system are: Relatively few regenerations of the carbon are possible before replacement is necessary; and the chromium which is stripped from the carbon (either with sulfuric acid or sodium hydroxide) is not always in a usable form. It would seem possible that the system is workable for concentrating the chromium for disposal by the conventional chemical destructive system.

Other Methods

A number of schemes have been proposed such as foam flotation, electrodialysis, solvent extraction, freezing, etc. None of these processes have found commercial application for the treatment of chromium wastes; however, as technology develops, these systems may have merit.

Summary

The standard method of treatment of chromium bearing wastes remains the chemical destructive system which has been used successfully for a number of years to control waste chromium in effluents. The EPA has concluded that "the best available demonstrated control technology has been determined to be the extensive use of in-plant controls and process modifications to minimize water use in combination with a well-designed and well-operated chemical treatment system to minimize the discharge of pollutants".[9] Additionally EPA advises that in process controls such as evaporative recovery, ion exchange, reverse osmosis, etc., can reduce costs by chemical conservation and water reuse, but some degree of chemical treatment may still be required.

It is anticipated, particularly for new point sources which would have engineering design capability, that process stream segregation would permit the use of various combinations of treatment techniques to achieve no discharge of process waste water pollutants.

Chemical treatment systems have been designed which can handle up to 100,000 gallons per day; however, for flow rates in excess of 25,000 gallons per day continuous flow-through systems should be considered to minimize equipment.

Recovery systems can show favorable economics if large quantities of valuable chemicals can be recovered and where water and sewer charges can be minimized.

Choosing the proper system which will comply with specific effluent regulations most economically will require a complete in-plant study by a competent engineer.

Analytical Methods

Hexavalent Chrome Trace Amounts

Diphenylcarbazide Method
Application:

For determination of trace amounts of hexavalent chromium, using a colorimeter. The method is recommended for analysis of rinse waters for effluents containingg trace amounts of Cr .

Technical Bulletin

Reagents and Equipment:

Sulfuric Acid -- 6N

Diphenylcarbazide Reagent -- 0.2 g. diphenylcarbazide dissolved in 100 ml ethanol and diluted to volume in a 500 ml volumetric flask with 1:9 H_2SO_4.

Colorimeter with light source in the range of 525 to 540 mμ. The Fisher Electrophotometer with a 525 mμ filter is adequate for this use.)

Procedure:

Place a sample containing 10-50 micrograms Cr^{+6} in a 100 ml Nessler tube (or 100 ml grad ate calibrated "to contain"). Dilute to 50 ml. Add 4 ml of 6 N H_2SO_4 and 3 ml of diphenylcarbazide solution. Dilute to 100 ml and mix thoroughly. Read % transmission at 540 mμ or using 525 mμ filter if Fisher Electrophotometer is used. Reading may be taken immediately if no vanadium is present. If vanadium is present, wait 10 min. before taking reading. Read micrograms of hexavalent chrome from calibration curve previously plotted with known quantities of potassium dichromate.

Calculations:

$$\text{ppm } Cr^{+6} = \frac{\mu\ +6}{\text{ml of Sample}}$$

$$\%\ Cr^{+6} = \frac{(\text{gms } Cr^{+6})\ (100)}{\text{wt. of Sample in gms}} \quad \text{Or} \quad \frac{\mu\ Cr^{+6}}{(10{,}000)\ \text{Sample Wt. in Grams}}$$

μ = micrograms

Calibration Curve:

Accurately weigh out 0.2830 g of $K_2Cr_2O_7$ and dissolve and dilute to one liter in volumetric flask to make a working solution. Pipette a 10 ml sample of working solution into a 1 liter volumetric flask and dilute to volume to make up standard solution. This standard solution contains 1 microgram Cr^{+6} in each ml of solution.

Using 5 -- 100 ml Nessler tubes (or 100 ml graduated cylinders calibrated "to contain"), pipette the following quantities of standard solution into each tube:

Tube No.	ml Standard Solution	$\mu\ Cr^{+6}$
1	10 ml	10
2	20 ml	20
3	30 ml	30
4	40 ml	40
5	50 ml	50

Dilute contents of each tube to 50 ml, add 4 ml of 6N H_2SO_4 and 3 ml of diphenycarbazide solution to each tube. Dilute to 100 ml and mix thoroughly. Read the % transmittance at 540 mμ for each of these solutions and draw a calibration curve showing % transmittance vs. μ Cr^{+6}

Technical Bulletin

Appendix II

Trivalent Chromium

Determination of trivalent chromium in the presence of hexavalent chromium in effluent streams. Trivalent chrome is separated and then oxidized to hexavalent state using perchloric acid. WARNING: An explosive reaction can occur if organics are present in sufficient amounts in persence of perchloric acid. Be sure all organic material is destroyed before adding perchloric acid. This can be determined by the absence of brown fumes during evaporation to dense fumes of sulfuric acid in this method. This procedure should be carried out in a hood as oxides of nitrogen are expelled.

Reagents:

Sodium Hydroxide, 10% solution
Nitric Acid, Concentrated
Perchloric Acid, Concentrated
Sulfuric Acid, Concentrated
Reagents from Trace Amounts Hexavalent Chromium

Preparation of Sample:

Pipette a sample containing 10-50 micrograms of Cr^{+3} into a 250 ml beaker and dilute to 100 ml. Neutralize the solution to a pH of 10 using alkacid test ribbon as the indicator.

Boil for 10 minutes, allow precipitate to settle and filter through a No. 40 Whatman paper. Police the beaker and wash the precipitate with distilled water until free of all hexavalent chromium.

Transfer the paper and precipitate to a 250 ml Erlenmeyer flask. Add 2 or 3 glass beads, 20 ml HNO_3, and 15 ml H_2SO_4. Fit flask with a vapor trap or a short stemmed funnel, and evaporate the dense fumes of sulfuric acid to destroy any organics present. Add 20 more ml of HNO_3 and 25 ml of $HCLO_4$ and evaporate to dense fumes of perchloric acid and fume for 2 minutes after the solution has turned orange. Cool rapidly, wash down sides of flask, and dilute to about 85 ml. Boil for 1 or 2 minutes to drive out chlorine fumes. Cool to room temperature and transfer to a 100 ml Nessler tube and determine the Cr^{+6} concentration using the diphenylcarbazide method.

Total Chromium

The total chromium concentration is simply the sum of the concentrations of Cr^{+6} and Cr^{+3}.

Additionally atomic absorption (AA) spectroscopy may be used to determine the total concentration of soluble chromium. With AA methods special wet techniques of separation must be made to determine trace quantities of Cr^{+6} and Cr^{+3}.

OCCURRENCE

Nickel and cobalt occur in the mining environment primarily around mining centers where they are produced such as Sudbury and Falconbridge, Ontario, and the huge Bushveld Igneous Complex in the Transvaal where both metals are produced as a by-product of platinum recovery operations. Nickel may be produced by smelting ore, by hydrometallurgical processes, or a combination of both, so it can be distributed through plant effluents or smelter gas fallout.

Several deposits are known or have been worked in the past where cobalt is the product of primary economic importance such as the Blackbird Mine in Idaho, a deposit in Missouri, and one in the Ontario cobalt district.

Small amounts of nickel and cobalt occur in the Witwatersrand gold-uranium ore. The quantity is not enough to be considered a valuable resource, except when cobalt prices rise to very high levels, but high enough to be a nuisance when it forms a cobaltic cyanide complex during gold leaching only to foul ion exchange resins used to recover uranium after the subsequent sulfuric acid leaching step. Surprisingly, a mine water samples from Witwatersrand Mines was recently analyzed to contain 8 mg/l Ni and 2 mg/l Co.

Nickel is also produced in New Caledonia where serious damage to the seabed ecology has been reported due to contamination by mine-mill tailings and the toxicity of nickel at very low levels to marine organisms. Jacques Cousteau has documented the effects of submarine tailings disposal at this site.

Cobalt and nickel are discussed together because of the common geochemical association of these two metals. Their chemistries are also similar.

Cobalt and particularly nickel are common contaminants in effluents from plating operations and nickel-silver recycling operations.

Modal concentrations of nickel in the upper Great Lakes are less than 5 ug/l but are often not detected in water intakes. There is some evidence of nickel contamination of Georgian Bay.

ENVIRONMENTAL SENSITIVITY TO NICKEL AND COBALT

Based on available information, freshwater toxicity of cobalt and nickel are lower than most other heavy metals such as zinc and mercury but more toxic than lead.

The toxicity of nickel is related to water hardness in fresh water with a relatively steep gradient as reflected in the U.S. EPA (1980) water quality criteria for this metal.

The ONTARIO MOE (1979) criterion for nickel in Ontario waters is set at 25 ug/l based on observed toxicity to Daphia magna.

Nickel in large doses causes dermatitis to man and lung cancer after chronic inhalation. Oral toxicity of nickel is extremely low.

Nickel is classed as very toxic to plants with toxicity observed at concentrations below 1 mg/l in a nutrient solution. Some fungi and plants adapt to grow in high Ni concentrations, however, and some algal populations have shown tolerance to nickel. This can be observed in the prolificmarsh area that forms part of the water management scheme at Falconbridge, Ontario, where algae thrive in the lime-treated recycle water with nickel levels close to 1 ppm.

Chronic three-week nickel exposures to Daphia magna caused 50% mortality at 130 ug/l and 50% and 16% reproductive impairment at 95 and 30 ug/l according to ONTARIO MOE (1979), which is the basis of Ontario's water quality criteria of 25 ug/l.

Acute toxicity of nickel to fish is less than that of copper or zinc and is in the 4-40 mg Ni/l range depending on the hardness of the water. The 48-hour LC_{50} for rainbow trout is 32,000 ug/l while those for copper and zinc were 750 and 4,000 ug/l respectively (BROWN and DALTON, 1970).

The only marine water criteria for nickel are those of the U.S. EPA (1980) which were developed on the basis of toxicity.

The 140 ug/l maximum permissible level of Ni in marine water has been considered acceptable, but the 7.1 ug/l 24-hour average criterion may be too strict since the lowest level of nickel ever documented to have a chronically toxic effect on marine organisms was greater than 61 ug/l. Most toxicity data for marine organisms indicate no toxic effects at concentrations below 1 mg/l. Shellfish bioaccumulate nickel.

No fresh or marine water criteria for cobalt have been formulated by the regulatory bodies of the main mining countries of the world.

REGULATORY EFFLUENT LIMITS - Ni AND Co

No effluent limits were identified for cobalt.

Effluent limits for nickel were identified as follows:

REGULATED EFFLUENT LIMITS - NICKEL (mg/l)

	Daily Maximum	30d Average	
Falconbridge Onaping, Ontario	1.0	1.0	Ni-Cu Mill
Key Lake Uranium Saskatchewan	1.0	0.50	Uranium Mill
Homestake Mining Lead SD NPDES	1.25	1.25	Gold Mill
Denison Mines Elliot Lake, Ontario	1.0		Uranium Mill
Cominco Ltd., Con Mine Yellowknife NWT	1.00	0.50	Gold Mill
Giant Yellowknife Mines Yellowknife, NWT	1.00	0.50	Gold Mill
New Mexico Water Quality Control Commission	0.10	0.10	General
South Africa	No Standard for Ni.		
Singapore	0.10	0.10	
Singapore to Sewers	10.00	10.00	
Rio de Janeiro State, Brazil	1.0		
Minas Gerais State, Brazil	1.0		
Sao Paulo State, Brazil	2.0		

NICKEL CONTAMINATION ABATEMENT

Good housekeeping and preventing nickel from getting into solution in the first place is the most important means of reducing the need and cost of nickel removal from the mine-mill environment.

When many of today's nickel mine-mill complexes were originally installed, the industry was not aware of many of the housekeeping factors that can influence nickel (and other metal contaminant) levels in effluents. An excellent case in point is the FALCONBRIDGE nickel mining, milling, and smelting operations at Onaping, Ontario, and at Falconbridge, Ontario.

It has been found that drainage from oxidizing wasterock used to build a half mile stretch of road alongside the present day final effluent stream results in an increase in the nickel level in the effluent of 0.1 mg/l. This illustrates the need for great care when using wasterock for construction of road and railbeds as well as service yards, etc.

Also at Falconbridge, Onaping, acid mine drainage containing relatively high levels of nickel is used as process water in the Strathcona mill-concentrator. In this way nickel is precipitated at the high process pH avoiding the need for an expensive treatment plant.

Another aspect of nickel housekeeping is how nickel and copper concentrates are stored and loaded. Windblown spillages of concentrates along railtracks and concentrate that works its way into the ground around loading and storage points both contribute to contamination of runoff water as well as groundwater and seepage. Such areas have been identified and reclaimed in some cases by processing the top several inches of soil through the mill.

A whole host of innovative water, tailings, and wasterock management items have been implemented at FALCONBRIDGE. A most significant improvement in factors that influence water quality has been the extensive gas cleaning steps ahead of the smelter stack which has greatly reduced the amount of metal-bearing particulates as well as acid forming SO_2 that would otherwise escape to the environment around the complex.

TREATMENT FOR COBALT AND NICKEL

Cobalt and nickel are complexed by cyanide to form extremely stable soluble complexes which interfere with both cyanide and nickel treatment.

Treatment for both nickel and cobalt can be destructive, such as precipitation and sludge disposal, or nickel values can be recovered.

PRECIPITATION OF NICKEL

Precipitation of nickel hydroxide is generally the basis for destructive treatment of nickel-bearing wastes. Precipitation with carbonate is most commonly associated with recovery systems in industrial operations where nickel is used.

Nickel forms insoluble nickel hydroxide on addition of lime. $Ni(OH)_2$ has a theoretical minimum solubility of 0.01 mg/l at pH 10 according to JENKINS, et al. (1964).

According to PATTERSON (1975), precipitation of nickel is most effective at a high pH, although little efficiency is gained by increasing pH above about pH 10.

PATTERSON (1975) reported limited application of sulfide precipitation for nickel wastewaters (LARSEN, et al., 1973; ROSEHART and LEE, 1972). In one case, gold ore extraction wastewater at 6.5 mg/l Ni was reduced to 2.1 mg/l Ni after treatment with sodium sulfide at pH 7. Use of alum at pH 7-8 on the same waste reduced nickel to 0.5 mg/l, and the use of lime or caustic at pH over 10 reduced nickel to below detectable limits.

Process	[Ni] in Treated Water
Untreated	6.5 mg/l Ni
Na_2S at pH 7	2.1 mg/l Ni
Na_2S + Alum pH 7-8	0.5 mg/l Ni
Lime or NaOH, pH 10+	LTDL

LTDL = Less than detection limit.

LARSEN, et al. (1973) added lime to pH 5.5-6.5 which reduced nickel levels of 0.19-0.51 mg/l to 0.13-0.29 mg/l. Subsequent pH increase and Na_2S addition reduced Ni levels much lower than this as described by LARSEN, et al. (1976).

Therefore, close pH control is not essential other than from considerations of chemical costs associated with pH adjustment. The following table from PATTERSON (1975) summarizes results of commercial scale effluent treatment plants installed in the metal finishing industry. Effluent nickel values of in excess of 1 mg/l appear to result from improper pH control according to NEMEROW (1963) and TUPPS (1961).

Summary of Effluent Nickel Concentrations after Precipitation Treatment.

Source	Nickel Concentration mg/l Initial	Final	Comments	Reference
Tableware Plating	21	0.09-1.9	$FeCl_3$ + Sand filtration	3
Appliance Manufacturing	35	0.4	—	4
Office Machine Manufacturing	39	0.17	Polyelectrolyte, 1-2 mg/l	19
Nonferrous Metal Works	—	0.05-0.13	6-hr settling	20
	—	0.05-0.13	pH = 8.5-9.0	21
	—	15	pH = 8.1	22
Plating	46	0.8	6-hr detention in circular clarifier	12
Record Changer Manufacturing	—	0.1-0.2	—	23

23 METAL FINISHING JOURNAL (1971)

CHEN and TAY (1979) tested a metal finishing waste containing 80 mg/l nickel in the laboratory and found that nickel removal by lime precipitation was increased from 63% to 81% by addition of 2-6 mg/l alum, while a dose of alum in excess of 6 mg/l resulted in a decreased Ni removal due to the decrease in pH. $FeCl_3$ dosage removed only 40% of the nickel at an optimal dosage of 2 mg/l, but this could be improved to 67% by addition of 0.1 mg/l polymer.

By adding 2.5 mg/l lime, 93% Ni removal was achieved, and at 15 mg/l lime dosage, nickel removal was 99%.

BaS dosage at 1 g/l removed 100% of the nickel from solution at pH 2. BaS addition also increased the pH of the solution. The NiS precipitate formed a dense and easily separatable floc.

At FALCONBRIDGE's Sudbury operations, nickel is reduced to 0.1 mg/l in solution after lime precipitation, and nickel levels increase in the marsh area after decantation due to pickup of nickel values from the area that was previously contaminated by smelter stackgas fallout.

RIVETT and OKO described limestone neutralization of waste water at FALCONBRIDGE's Onaping mines. Demonstrating the effects of retention time and neutralizaton from pH 3.5 to pH 7.2 with limestone, the nickel level was reported at 0.6 ppm in the tailings dam water, 0.3 ppm at the inlet to the neutralization dam, and 0.3 ppm Ni after neutralization. This shows that neutralization with ground limestone does not reduce nickel levels in the effluent as a high enough pH is not reached. In 1984, the same operation was visited, only this time nickel levels were around 0.8-0.9 ppm by the time the solution reached the outlet from lower Moose Lake. A further 0.1 ppm Ni was added between the lower Moose Lake overflow point and discharge to the receiving waters due to seepage from the roadbed. It is believed that some as yet unidentified biological nickel removal process occurs in Upper Moose Lake.

Also, at FALCONBRIDGE's Onaping mine, NaOH solution was used for final pH adjustment to precipitate nickel from a small stream of mine water. After addition of the NaOH, the neutralized solution flows to a settling pond with a baffle. Two points of interest arose. First, NaOH was selected for pH adjustment because, due to use of cement in backfill, the mine water was pumped to the surface at an already high pH, and very little reagent was needed and only sometimes. However, when the mine operation was interrupted and no backfill was pumped underground, the mine water pH dropped, and the NaOH consuption needed to precipitate nickel became much more expensive.

Secondly, mine sewage was dumped into the same decant pond. The result was that due to bacterial action, gas bubbles formed from the sewage in the pond sediment. These attached themselves to $Ni(OH)_2$ sediment from the bottom of the dam with the result that 5% Ni precipitate was being transported from the pond via its overflow.

SCHILLER and KHALAFALLA (1983) describe a new patented process for removal of Cd, Cr, Cu, Fe, Mn, Ni, Pb, and Zn from wastewater. Specific areas of application include treatment of mine drainage and metal finishing and metallurgy wastewaters. Disadvantages of the prior art are largely overcome by the use of a substantial excess of essentially dry, powdered, reactive MgO as a precipitatant in place of conventional precipitants. The resulting precipitate settles rapidly to a small volume and is not readily redispersed or redissolved. The purified water may be removed by decantation, thus avoiding the necessity of filtration. The technology is available for licensing from the U.S. Dept. of the Interior. The patent application contains very limited information on the process performance.

S. T. Herman of BETHLEHEM INTERNATIONAL ENGINEERING COMPANY (Bethlehem Steel) showed that lime precipitation using the HDS process can reduce dilute effluent solutions of Cu, Cd, Ni, Pb, and Zn to less than 0.1 ppm at a single pH level which would not be possible with conventional neutralization. Also, a settled sludge density of over 20% is achieved compared with the usual 1% solids achieved by conventional neutralization. In addition, BETHLEHEM STEEL has developed an innovative way of

stabilizing HDS sludges using pozzolonic reactions which render the sludge suitable for disposal in a sanitary landfill. More information is available from:

BETHLEHEM INTERNATIONAL
ENGINEERING CORP.
Bethlehem, PA 18106
(215) 694-2424

MIKHNEV, et al. (1978) describe the use of a sulfide solution in $Ca(OH)_2$ to precipitate heavy metals from metallurgical plant effluent. The Cu, Ni, and Fe were precipitated at pH 5.2, 7, and 7-9 respectively. The degree of removal depended on pH and the composition and dosage of the added $Ca(OH)_2$-$S^=$ solution, and to a very limited extent, on temperature (20-80°C). The treatment at final pH 7.5-8 decreased the metal concentrations as follows:

	Inflow	Outflow
Cu (mg/l)	70	0.1
Ni (mg/l)	80	0.01
Fe (mg/l)	10	0.01

The precipitate contained about 12% Cu, 12% Ni, and 20% CaC as CuS, NiS, and $CaSO_4$.

Importantly, the use of $Ca(OH)_2$-$S^=$ solution increased the clarification rate by 50-100%.

ION EXCHANGE

Recovery of nickel by ion exchange has been used for some time in the metal finishing industry although not in the mine-mill effluent treatment. It is unlikely that ion exchange will be competitive with lime precipitation for nickel removal from solutions encountered in mines and mineral processing.

Nickel cyanide permanently loads onto ion exchange resins according to SILMAN (1971) as does cobalticyanide.

SLATER, et al. (1978) tested a fluidized bed continuous ion exchange unit to treat a synthetic mine water containing 56 ppm Cu, 3.5 ppm Ni, 0.3 ppm Co, 1 ppm Fe, and 20 ppm Ca at pH 4 using strong acid resin, Amberlite 200C [54077-23-5] in the sodium form. After a five minute upflow period, loaded resin was transferred to an elution column where a saturated NaCl was used for elution. More information on the results may be available from the authors:

Gordon Ritcey at CANMET would like to continue these experiments using new resins and the latest CIX concepts which he feels could recover metal values as a resource.

ISUMI, et al. (1976) described a method for recovering heavy metals including cobalt from dilute solutions by foamy complex formation with N-monodecanoyl diethylenetriamine. [N-[2-[C2-aminoethyl)amino]ethyl]decanamide] which forms soluble and foamy complexes with metals.

ZAKIROV, et al. (1981) described the use of polygorskite clays of the Tappok deposit and their use in the treatment of nonferrous metallurgical effluents. Optimal adsorption capacity of the clays for cobalt in simulated wastewater was observed at 16 mg Co/l.

CHIN and TAY (1979) tested Amberlite Resin RI-120 for nickel removal from an acid effluent from a metal finishing plant and found a mass transfer coefficient (ka) of 1.92 g/min-Cm^3. They conclude that chemical precipitation of nickel followed by IX would yield effluents suitable for discharge to the municipal sewer at an estimated cost of S$0.68/$m^3$.

REVERSE OSMOSIS

GOLOMB (1972, 1973) showed in pilot plant studies that plating rinse water could be treated by reverse osmosis with 99.6% rejection of nickel at 1973 cost per 1,000 U.S. gallons of $3.08-$6.08 for relatively concentrated solutions around 1700 mg/l Ni. DONNELLY, et al. (1974) found that the relative efficiency of recovery was dependent on the type of membrane and module used with rejection ranging from 70-98% for plating wastes.

Mining industry effluents are unlikely to contain nickel at levels that justify R.O. treatment unless R.O. is installed for another reason.

Interestingly enough, mine water from the ERPM Hercules Shaft contains 8 ppm Ni and 2.0 ppm Co which, in a pilot scale seeded slurry R.O. test, yielded a product with 0.3 ppm Ni and 0.10 ppm Co.

COBALT AND NICKEL

	Influent (mg/l)	R.O. Product (mg/l)	Removal (%)
Ni	8.0	0.30	96%
Co	2.0	0.10	95%

The highly innovative seeded slurry reverse osmosis technology developed by RESOURCES CONSERVATION COMPANY is described in Chapter 15 and in the trip report on ERPM in Appendix I, also by HERRIGEL (1984).

In this case, the aim of the development program was to find a simple, low cost way to remove TDS from mine water prior to its discharge, and removal of Co, Ni, and other heavy metal ions is purely incidental--yet, nonetheless, it is a good demonstration of the effectiveness of R.O. for Co and Ni removal and concentration.

WILMOTH, et al. (1979) compared lime neutralization, reverse osmosis, and ion exchange for removal of As, Cd, Hg, Ni, Se, and Zn from acid mine drainage. Reverse osmosis and ion exchange were found to be slightly more effective overall than neutralization, but the chemical requirements for IX and the need for subsequent concentrate treatment offset their advantages. It is believed that the seeded slurry R.O. system in conjunction with an innovative tubular R.O. system may make it worthwhile reevaluating R.O. for some applications.

SASTRI (1978) reviewed a process for reverse osmosis removal of nickel from dilute solutions. Subsequently, the same author has been involved in development work in the use of low pressure reverse osmosis for metal recovery from low grade effluents.

Copper, lead, and zinc removal are reviewed together as these three base metals often occur in mine and mill effluents together, frequently with iron and other contaminants at a low pH.

Copper, lead, and zinc have some comparable aspects in their chemistry and behavior. For example, they all form hydroxide precipitates, and each forms a sulfide precipitate that is less soluble than its hydroxide. Carbonate chemistry can be used to advantage for the removal of lead to levels below that achievable by straightforward lime or NaOH precipitation.

Zinc and lead form hydroxide complexes, e.g., $[Zn(OH)_3]^-$ which means that beyond a certain pH, the solubility of zinc increases with further addition of hydroxide ions.

The removal of copper, lead, and zinc from solution is discussed in Appendix I in the following trip reports:

PEDCO (1983): Cu, Pb, AND Zn SUMMARY

The U.S. EPA commissioned a huge survey of U.S. mining and milling operations to determine levels of contaminants in minewater, acid mine drainage from tailings, and runoff areas, as well as potentially leachable contaminants from solids by the EP Leach Test which uses acetic acid.

Of the hundreds of samples analyzed for uranium, phosphate, copper, lead-zinc, molybdenum, gold-silver, and taconite recovery operations, most were at extremely low levels for copper, lead, and zinc. Examples of the small percentage where Cu, Pb, or Zn were detected are shown below.

It is concluded that:

1) Considering the levels of copper, lead, and zinc in ores, it is rather surprising to see how low the levels of copper, lead, and zinc are in tailings pond liquid and minewater. Nonetheless, levels are reached which clearly require removal before these solutions can be discharged, but this is not so in many cases.

2) Acetic acid leachate of solids extracted lead which, in most natural occurrences would be fixed as a carbonate or sulfate. Lead forms an acetate complex, but acetic acid does not occur commonly in nature, so the validity of the test is questionable.

3) Within each industry group, there is a wide range of Cu, Pb, and Zn levels in the effluents and leachates which reinforces the need for site specific criteria.

HIGH LEVELS OF EP TOXICITY CONTAMINANTS

IN THE LEAD/ZINC MINING SEGMENT
(mg/liter)

Analytical parameter	District		
	Eastern	Western	Missouri
Lead	5.0[a]	8.8[a], 11.0[b], 16.0[b], 5.5[e]	23.0[c], 39.0[d]

Waste types:
a - Tailings pond settled solids (two occurrences).
b - Fresh tailings (two occurrences).
c - Underground mine waste rock (one occurrence).
d - Mine water pond settled solids (one occurrence).
e - Mine backfilled tailings (one occurrence).

ELEVATED LEVELS OF EP TOXICITY CONTAMINANTS
IN THE LEAD/ZINC MINING SEGMENT
(mg/liter)

Analytical parameter	District		
	Eastern	Western	Missouri
Cadmium	0.65[a]	None	None
Lead	1.2[b], 2.4[b], 1.4[b]	4.6[c], 2.1[d], 1.0[e]	3.6[b], 1.9[f]
Mercury	0.041[c]	None	None

Waste types:
a - Inactive surface mine waste rock (one occurrence).
b - Tailings pond settled solids (four occurrences).
c - Fresh tailings (two occurrences).
d - Mine backfilled tailings (one occurrence).
e - Underground mine waste rock (one occurrence).
f - Coarse tailings dike material (one occurrence).

Source: PEDCO (1983)

HIGH LEVELS OF EP TOXICITY CONTAMINANTS
IN THE GOLD/SILVER MINING SEGMENT
(mg/liter)

Analytical parameter	District	
	Nevada	Other
Lead	None	11.0[a], 17.0[b], 23.0[c], 100.0[c]

Waste types:
a - Underground mine waste rock (one occurrence).
b - Fresh tailings (one occurrence).
c - Tailings pond settled solids (two occurrences).

ELEVATED LEVELS OF EP TOXICITY CONTAMINANTS
IN THE GOLD/SILVER MINING INDUSTRY
(mg/liter)

Analytical parameter	District	
	Nevada	Other
Cadmium	None	0.30[a], 0.36[a]
Lead	None	4.6[b], 4.9[c], 3.7[a]
Mercury	0.043[d]	None
Selenium	None	0.67[d]

Waste types:
a - Tailings pond settled solids (three occurrences).
b - Low-grade ore (one occurrence).
c - Underground mine waste rock (one occurrence).
d - Fresh tailings (two occurrences).

COPPER

Eh-pH diagrams for copper given by GARRELS and CHRIST (1964) suggest that copper oxide or hydroxy-carbonate minerals would tend to limit the solubility of copper in aerated water at pH 7.0 to about 64 mg/l. At pH 8.0, the solubility would be about one tenth as great or about 6.4 mg/l. Copper solubility is generally lower in reducing systems than in oxidizing systems, especially if reduced sulfur species are present.

Copper is a widely distributed element, and the amounts of copper reported in river water by DURUM and HAFFTY (1963) are within the general range predicted from the solubility calculated by GARRELS and CHRIST (1964).

Besides the natural occurrence of copper, the metal is used extensively in water treatment equipment and in the fabrication of pipe, valves, and pumping equipment. Small amounts of copper sulfate are commonly added to water stored in reservoirs to inhibit algal growth. Most of the higher concentrations reported by DURFOR and BECKER (1964) for public supplies were in water which had been impounded in storage reservoirs and treated in this way.

High concentrations of copper up to hundreds of ppm may occur in acid mine drainage from open pit and underground mine workings, ore dumps, or mill tailings. Copper contents in ground and surface water can be high in areas where ore bodies occur. MALIUGA (1950) found an average of 200 mg/l Cu in water from a mineralized region in the southern Urals of the U.S.S.R., but one would not have to go that far to find elevated copper levels in AMD. Geochemical literature contains much data on copper concentrations in water from such areas.

Concentrations of copper in the Great Lakes are dependent on local inputs. In parts of Lake Superior and elsewhere, copper concentrations are shown to rise in the spring. Modal copper concentration in upper lakes offshore are less than 2.5 ug/l with 95% of the measurements below 5.0 ug/l. Water intakes to the lakes varied between 2 and 60 ug/l, probably influenced by local industrial and municipal sources.

Sediments in Lake Erie deposited in pre-colonial times contain about 27 ug/g copper compared with 57 ug/g for recent sediments indicating that man's activities account for 50% of the total input of copper in Lake Erie according to KEMP, et al. (1976).

WILLIAMS and MINK (1975) analyzed the levels of Cu, Pb, Zn, Cl, F, Ca, Cd, Fe, K, Mg, Mn, Na, and Sb in the inflow and effluent from the settling ponds of seven mines which produce lead, zinc, and silver in Idaho. The outflow from five settling ponds that received only effluent from the concentrating process were acceptable, but the outflows from two ponds that received concentrator effluent plus acid mine drainage and wastes

from various processes contained "high" concentrations of F, Cd, Cu, Pb, Zn, and Sb according to the Idaho Bureau of Mines and Geology, Moscow, Idaho.

A typical analysis of water from the Burra-Burra Mine, Ducktown, Tennesee, dated 1911, from HEM (1970) shows a typical acid mine drainage analysis from a copper mine:

	mg/l
SiO_2	56
Aluminum	433
Iron	2,178
Manganese	0.2
Copper	312
Zinc	200
Calcium	68
Magnesium	41
Sodium	23
Potassium	20
Bicarbonate	0
Sulfate	6,600
Chloride	0.1
TDS	9,990
Acidity as H_2SO_4	130

Total copper in water is usually in the form of insoluble particulates, soluble complexes, and soluble Cu^{2+} ions. The proportion of each form depends on the amount of particulate and soluble complexing agents. These agents, according to STIFF (1971), may be materials such as humates or carbonates.

PATTERSON (1975) reported copper levels in effluents as follows:

Process	Copper Concentration mg/l	Reference
Copper Ore Extraction	0.28-0.33	TALLMANGE (1965)
Gold Ore Extraction	20	HALLOWELL, et al. (1973)
Acid Mine Drainage	3.2	HILL (1972)
Acid Mine Drainage	3.9	HILL (1972)
Acid Mine Drainage	0.12	HILL (1972)
Acid Mine Drainage	51.6-128.0	LARSEN, et al. (1973)

In the course of this investigation, recycled process solutions, mine drainage effluents, and treated effluents were encountered with compositions shown at the front of this chapter. Metals, Pb, Zn, Fe, and pH, are shown to provide perspective. It is concluded that:

- Acid mine drainage and surface drainage where copper is present can reach levels in the hundreds of ppm. Some mines where mine drainage has a high pH, e.g., Kidd Creek Mines, never see copper above 0.1 ppm as it is precipitated by the water in the mine. Underground sludges contain 2-3% copper at times.

- Treated effluents contain low copper values, generally below 0.1 ppm and often as low as 0.01 ppm.

- Ammonia is a powerful complexing agent, and it is not detected from the data whether relatively high ammonia levels in minewater prevent copper from being precipitated by lime. This does not appear to be the case.

- In recycled mill solutions, especially in copper-lead-zinc flotation plants, soluble copper must not be allowed to build up. Copper is an activator for sphalerite and, if present in mill solutions, will cause sphalerite to float in the primary separation where Cu-Pb is floated as a semi-bulk rougher ion while sphalerite is depressed. At one Cu-PbZn mine-mill in British Columbia, the presence of a small amount of oxidized copper ore in the mill feed wreaked havoc with separations achieved in the mill due to copper solubilization.

In the course of this investigation, copper was encountered in the following metallurgical process solutions, effluents, acid mine drainage, etc:

LEAD

The chemistry of lead in natural waters has been indicated in Eh-pH diagrams by GARRELS and CHRIST (1964). Over most of the water stability region, the oxidation state of lead is Pb^{++}, and the most likely control of solubility in oxidizing systems is the carbonate, cerussite. Lead sulfate $PbSO_4$ is relatively insoluble and will control lead in oxidizing systems, especially those associated with sulfide mines where sulfate is always abundant in waters that come into contact with ore, tailings, and wasterock. In the presence of sulfides in water, lead sulfide precipitates with a solubility around 2 mg/l. The carbonate, hydroxide, phosphate chloride, sulfide, and sulfate of lead all have very low solubilities in water.

The ONTARIO MOE (1979) reported median lead offshore values of less than 1.0 ug/l in Great Lakes waters. A median value of 3.7 ug/l of lead for public water supplies was

reported by DUFOR and BECKER (1964), although lead was not detected at all in many samples. The median value for North American rivers reported by DURUM and HAFFTY (1963) was 4.0 ug/l. The wide use of lead as a gasoline additive and its dispersal in engine exhaust has considerably increased the availability of lead for solution in rainfall and fresh water but, according to HEM (1970), the importance of that effect was not known except, of course, in the banning of new cars that use leaded fuels.

Lead contained in zinc flue dusts used as fertilizer additives is added to soils as a plant food despite the fact that lead, even at 1.0 mg/l in the nutrient solutions, is toxic to plants. A common problem in wetlands is lead pellets ingested by wildfowl where just 5-6 pellets are lethal.

Metal mining and concentrate smelting introduce lead into the environment although the levels encountered in minewater were surprisingly low. Lead smelter recycle water contained 10 ppm lead, probably mostly in the form of suspended solids which are reduced to 0.04-0.50 mg/l on lime addition and settling.

Significant lead values have been found in minewater. One example is municipal water pumped from an abandoned mineshaft in Australia which was used as a municipal water supply infiltration gallery and was reported by the AUSTRALIAN DEPT. OF MINES (1962). MILL (1972) reported the following lead levels in acid mine drainage at low pH values where lead would be predominantly in soluble form:

Source	pH	Lead (mg/l)
Tailings Pond	2.0	0.67
Mine Drainage	2.6	0.30
Mine Drainage	3.2	2.5
Mine Drainage	-	0.02

ZINC

Zinc occurs commonly as sphalerite, a sulfide mineral. Zinc is commonly present in carbonate rocks, and its geochemistry has been described by WEDEPOHL (1953).

The weathering of zinc minerals in contact with air releases zinc ions. HEM (1970) showed an example of acid mine drainage from the Victor Mine, Joplin, Missouri, that contained 345 mg Zn/l in 1917.

Data gathered during this RANDOL investigation showed zinc at 9300 mg/l in a Jarosite pond solution, and 0.10-800 mg/l in some acid mine drainage flows. A mine does not have to be a base metal mine to have zinc in its minewater--for example, an Elliot Lake uranium

minewater contained 4.50 mg/l zinc, and gold-silver cyanidation plants use zinc to precipitate the precious metals, allowing the zinc to go into solution as a cyanide.

Zinc is a widely used metal and can be dissolved from galvanized pipe, fences, and construction steel in many forms and uses. It may also be present in industrial waste and is added as a nutrient supplement in fertilizers and animal feed.

The solubility constant for zinc hydroxide quoted by SILLEN and MARTELL (1964) is around 10^{-17} at 25°C. According to HEM (1970), the equilibrium activity of Zn^{++} at pH 8.00 in the presence of $Zn(OH)_2$ is about 650 mg/l. As pH increases, the solubility passes through a minimum and then increases as $[Zn(OH)_3]^-$ is formed. The solubility of zinc carbonate is in the same range as the hydroxide, and concentrations of zinc in solution at well above 1 mg/l can be stable at neutral pH.

Zinc is often present in natural waters at concentrations well above that which would be in equilibrium with $Zn(OH)_2$ or $ZnCO_3$. In southwestern Wisconsin, some springs near known ore deposits contained 1500 mg/l Zn in contrast to background levels of around 10 mg/l.

At a reclaimed minesite in Quebec, galvanized articles in the burned garbage dump of the former operation and residential area introduced enough zinc to percolating solutions to necessitate diversion of runoff from the area to minimize uptake of zinc from this area.

Zinc also enters the environment through the burning of fossil fuels containing zinc and in effluents from synthetic fabric treatment, e.g., rayon.

According to the ONTARIO MOE (1979), modal concentrations of zinc offshore in the Great Lakes are less than 10 ug/l with concentrations ranging from 1.0 ug/l to 28 ug/l. At water intakes to the lakes, zinc concentrations were considerably higher, e.g., 178 ug/l at Buffalo.

WATER QUALITY CRITERIA, CU, PB, AND ZN

Water quality criteria to protect fresh and marine aquatic life as summarized by NORANDA RESEARCH are tabulated on the previous pages.

The EPA (1980) objectives to protect freshwater aquatic life is a log function:

Copper

$$[Cu] = e^{(0.94\ [\ln \text{hardness}]\ -1.23)}$$

This computes as follows:

Hardness	50 mg/l	200 mg/l $CaCO_3$
[Cu] Max.	12 ug/l	43 ug/l

Lead

$$[Pb]\ Max. = e^{(.22\ [in\ hardness]\ -0.47}$$

This computes as follows:

Hardness	50 mg/l	200 mg/l $CaCO_3$
[Pb] Max.	74 ug/l	400 ug/l

Zinc

$$[Zn]\ Max. = e^{(0.83\ [in\ hardness]\ +\ 1.95}$$

This computes as follows:

Hardness	50 mg/l	200 mg/l $CaCO_3$
[Zn] Max.	102 ug/l	570 ug/l

ENVIRONMENTAL SENSITIVITY TO Cu, Pb, AND Zn

Copper

It would appear that the 2.0 ug/l Canadian objective for fresh water copper levels is very strict, as may be the U.S. EPA 24-hour limit objective of 12-43 ug/l copper for fresh water and 4 ug/l for marinewater.

The objectives appear to be based on laboratory bioassay tests in which Cu^{2+} ions were added to laboratory water rather than real life waters which contain complexing agents such as carbonate, phosphate, amino acids, humic acid, lignins, and suspended organic and inorganic materials according to STIFF (1971).

Critics have commented on the need to distinguish between total and ionic copper in setting environmental objectives.

The ONTARIO MOE (1979) recognizes the various ways in which copper is present in water and recognizes that methods of distinguishing between toxic and non-toxic copper have not been applied in laboratory studies which are based on total copper introduced as cupric ions.

In public water supplies, copper presents an aesthetic rather than toxicity problem. The U.S. drinking water standard is set at 1,000 ug/l to control taste (U.S. PHS, 1962).

Concentrations of copper that are toxic to organisms vary considerably with hardness and alkalinity of water because concentrations used during short-term LC 50 tests are close to the limits of solubility.

Freshwater algae are sensitive to copper. Generally, 200-800 ug/l inhibit algal life functions according to WONG (1975).

NIELSON, et al. (1969) showed that photosynthesis of Chlorella pyrenoidosa was reduced 60 percent by only 20 ug/l copper, and that toxicity of copper varied with exposure time, light intensity, initial cell concentration, and composition of the medium. Copper and nickel synergistic effects on algae have been noted as well as heavy metal tolerance by STOKES and HUTCHINSON (1975).

Numerous aquatic species were adversely affected at copper levels between 4-15 ug/l. Reproduction of Daphnia magna were reduced 16 percent at 22 ug/l and 50% at 35 ug/l after three weeks in Lake Superior at 45 ug/l hardness.

Atlantic salmon (Salmo salar) avoided 2.4 ug/l copper in the laboratory and, in a famous experiment in a New Brunswick river, a spawning run of adult salmon was reversed when copper and zinc levels were 19 an 240 ug/l according to SPRAGUE, et al. (1965).

The ONTARIO MOE (1979) shows numerous references to evidence of damage to trout, bluegills, and minnows at copper levels of around 10-20 ug/l.

Testwork suggests no food chain bioaccumulation in the muscle of fish and shellfish.

EATON (1973) found that low levels of Cd and Zn, if present with 5-7 ug/l copper, will have an adverse effect on fathead minnow reproduction.

It is recognized that very much more needs to be learned about copper toxicity in its various modes of occurrence, but it is also clear that copper even at very low levels has a detrimental effect on aquatic life.

Lead

Lead toxicity is highly dependent on the alkalinity of water. Toxicity decreases with increasing alkalinity. Lead forms insoluble compounds in water including carbonate, hydroxide, phosphate, chloride, and sulfates which precipitate it from solution. The percentage of lead that is precipitated when a solution is added to Lake Ontario water was found to be:

Concentration Added	Degree Precipitated
100 mg/l Pb	98% Plus in 24 Hours
10 mg/l Pb	70% Plus in 24 Hours
1 mg/l Pb	10% in 24 Hours

For example, a hardness of 24.0 mg/l, alkalinity of 22.8 mg/l $CaCO_3$, and pH 6.91, about 100 percent of lead present below 100 mg/l is in dissolved form. Above pH 8, lead solubility is less than 10 ug/l regardless of alkalinity (HEM and DURUM, 1973).

Total lead concentration in unpolluted inland Ontario waters is usually less than 10 ug/l, and modal lead concentrations in the upper Great Lakes waters are less than 1.0 ug/l offshore with 95% of all samples containing less than 3.0 ug/l.

Lead is not essential for plant and animal growth and is quite toxic. BOWEN (1966) rated lead as very toxic to plants, even below 1 mg/l in nutrient solutions.

HARDNESS AS CaCO3, mg/L

Just 5-6 shot pellets ingested orally are lethal to a mallard and 12-25 to a Canada goose (NRCC, 1973), and toxicity varies with diet.

Lead is extremely toxic to humans and animals, and the recommended maximum level for lead in livestock watering is 100 ug/l (NAS/NAE, 1973).

Because of a variation in hardness and alkalinity, the Ontario MOE objective for lead is different for each lake, e.g.:

Lake	Hardness (mg/l)	Alkalinity (mg/l)	Safe-Unsafe (Pb ug/l)
Superior	44	41	15-25
Huron	94	75	21-38
Michigan	119	--	25-46
Erie	123	91	25-48
Ontario	135	90	26-52

It is recognized by the ONTARIO MOE (1979) that the effects of lead methylation in lake sediments may reduce the toxicity of lead, but this had yet to be demonstrated or proven.

Mining industry observers have commented that the Canadian objectives of 5-30 ug/l lead, depending on water hardness, are reasonable based on the documentation available, but the U.S.A. EPA level of 0.75 ug at 50 mg/l hardness - 20 ug/l at 200 mg/l hardness do not seem to be substantiable.

Water hardness and alkalinity affect the toxicity of lead, and pH greatly affects both the solubility and the toxicity of lead.

Zinc

Zinc is an essential element for both plants and animals. Zinc is necessary for reproduction, growth, the formation of DNA and RNA, promotes wound healing, and has several other important roles in human and animal health.

Zinc toxicity to land plants is very rare. Zinc is non-toxic to man, even up to 40,000 ug/l Zn in water. The U.S. drinking water recommendation is based on taste at 5000 ug/l (NAS/NAE, 1973).

Concentrations of zinc inhibiting freshwater algae growth range generally between 1,000-10,000 ug/l according to WONG (1975); however, some algae species are much more sensitive and are affected at around 200 ug Zn/l.

Aquatic invertebrates are more sensitive to zinc than algae. Daphnia magna are affected in increasing degrees between 70 and 158 ug/l according to BIESINGER and CHRISTIANSEN (1972).

Fish are more sensitive to zinc than other aquatic organisms. Cases of complete mortality at 267 ug/l zinc and 0-29% mortality at 75 ug/l Zinc have been observed.

There is evidence that if the eggs if rainbow trout are pre-exposed to zinc, then safe-unsafe concentrations were 135-251 ug/l zinc according to GOETTL, et al. (1973).

It is believed that hatcheries in Colorado producing trout fry to stock Rocky Mountain streams in areas affected by acid mineral drainage pre-expose the trout eggs to metals in order to acclimatize the fish.

Avoidance of zinc may also prevent the reproduction of Atlantic Salmon. In the laboratory, juvenile salmon avoided 54 ug/l zinc while in the field, migration of adults was prevented by 240 ug/l Zn (SPRAGUE, et al., 1965) when there was also 19 ug/l copper present in the field test.

Zinc toxicity appears to vary with concentrations of other metals such as Cu and Cd. Concentrations of zinc causing sublethal harm to aquatic biota do not appear to vary significantly with hardness or alkalinity according to the ONTARIO MOE (1979), but the EPA found a definite link between zinc toxicity and hardness.

Bioaccumulation effects of zinc in fish muscle appears minimal although zinc in the muscle of seven species of fish which, in Lake Huron contained 4.69 ug/g Zn, contained 36.01 ug/g zinc in Toronto Harbor. The maximum accumulation of zinc in fish is in the gills and kidneys. In fish killed by zinc uptake, the ratio of zinc in gills to zinc in bones was dramatically increased.

Very low zinc level criteria levels of 30 ug/l in Ontario Lakes were established because of the great sensitivity of fish to low levels of zinc in water. Receiving stream guidelines of 30-570 ug/l Zn as maximum permissable concentrations have been selected by different regulatory agencies in North America. Observers feel that acclimatization has not been property taken into account.

REGULATIONS AND PERMITS - Cu, Pb, AND Zn

Levels of Cu, Pb, and Zn stipulated as maxima in permits for mines and mills encountered during this investigation are summarized below.

It is clear that there is a wide variation from one operation to the next and that most permits are considerably more lenient than the objectives set by regulatory bodies for these three metals. One reason for this is that the objectives are for the receiving waters, and the permit is written for the effluent being discharged.

It is important to note that most of the U.S.A. has to meet zero discharge for mills and tailings although minewater may be discharged subject to permits such as those shown below.

METALLURGICAL INTERFERENCES OF COPPER, LEAD, AND ZINC

Copper

Copper has been found to interfere in metallurgical operations in several ways. The most common is in the recovery of gold and/or silver by cyanidation of ores, concentrates, or calcines containing cyanide soluble copper.

For each mole of cyanide soluble copper in the gold-bearing feed, at least five moles of sodium cyanide must be added to be able to leach gold effectively. Some gold ores are so rich in cyanide soluble copper that 10-12 Kg NaCN/t is required to recover this gold by cyanidation, while an equivalent amount of copper cyanide complex is dissolved. Several gold ores have been rendered uneconomic in this way. Two highly innovative new process technologies are now offering promising solutions to the problem. First is a cost effective way to recover cyanide from copper cyanide in solutions or pulps. The other is an oil agglomeration physical recovery process for very fine gold particles from high copper ores.

Even ores with low levels of copper result in relatively high concentrations of copper in cyanide solution in the pulp when barrens are recycled. Ultimately, a level is reached at which the base metal sulfides interfere with zinc precipitation of gold. When this occurs, copper and other base metals are bled from the system in a so called barren bleed. Since the barren bleed contains high levels of copper and other base metals as well as cyanide, this barren bleed represents an effluent disposal problem. Numerous gold mills around the world dispose of barren bleed solutions in one way or another.

Another interesting effect of soluble copper on metallurgical circuits is in complex sulfide flotation circuits. A typical arrangement is to float a Cu-Pb sulfide concentrate in a semi-bulk float while depressing sphalerite in this primary recovery step.

Copper sulfate is commonly used as an activator for sphalerite in the subsequent flotation of zinc.

If copper gets into solution in the recycled process water or for any other cause, then there is a good possibility that the selectivity of flotation will be seriously impaired. Problems of this sort are described in the trip report on BLACK MOUNTAIN MINING AND DEVELOPMENT CO. in Appendix I. In this case, extensive recycle of water resulted in a buildup of copper ions in process water.

McTAVISH (1985) described a similar situation where it was virtually impossible to recover cleanly separated concentrates from a copper-lead-zinc ore. These metallurgical problems occurred at NORANDA's Goldstream project in British Columbia despite extensive pilot testwork which gave no reason to anticipate them. Finally, it was found that a thin layer

of the open pit ore near the surface contained enough water soluble-copper to introduce enough soluble copper with mill feed to do severe damage. Since open pit ore was mined in "slices," there was a continual source of the trouble-causing oxidized layer which was blended with underground ore and deeper open pit ore. Soluble copper levels of 5-10 ppm were measured in the process solution. In this case, the problem was solved by isolating the water soluble oxide copper ore which represented but a tiny fraction of total feed and ultimately, design tonnages, recovery, and grade were achieved for all three concentrates before Goldstream shut down due to metal market conditions.

More information can be obtained about this most interesting problem and the simple answer that was found from:

NORANDA MINES LTD.
Goldstream Mine Site
Post Office Box 2970
Revelstoke, B.C. V2C 250
(604) 837-9312
S. McTavish

Although the root of the problem at Black Mountain and at Goldstream is probably quite different, in both cases soluble copper had a similar effect on the metallurgy of not too dissimilar copper-lead-zinc ore treatment.

Lead and Zinc

No serious metallurgical problems were encountered as a result of zinc and/or lead in solution. If zinc levels get too high in gold cyanidation circuits, then this contributes to a foul liquor and necessitates a barren bleed. Lead in high pH values will invariably precipitate as a carbonate or sulfate before it becomes a nuisance metallurgically.

Lead nitrate or lead acetate is often added in gold milling circuits that contain soluble sulfides as a means of controlling cyanide consumption and improving recovery.

TREATMENT FOR COPPER, LEAD, AND ZINC

Each of these metals can be removed from solution using the same basic processes, e.g., precipitation by hydroxide or sulfide, and ion exchange. The response to each process is somewhat different for each of the metals, however. There are several frontier processes which have the potential for development into useful and economical processes.

During the course of this investigation, which focuses on the mining and mineral processing industry, the most commonly employed process encountered at this time is lime precipitation and settling although ion exchange is in use to recover an economical copper resource from an effluent at El Teniente, Chile. Sulfide precipitation on a commercial scale is employed at BOLIDEN MINERAL AB's Skellefteham smelter operation. Attempts to recover zinc economicaly by ion exchange have been a technical success but an economic failure. Of the three metals, lead appears usually to be the least troublesome in mining and metallurgical solutions, probably because of the frequent presence of sulfate, carbonate, and chloride ions in the mine-mill environment which precipitate lead.

Although, in many cases, copper, lead, and zinc levels in mine-mill effluents (after lime precipitation) comply with effluent discharge permits currently in force, there is clearly still pressure on and by regulators to lower the permissible dischargable effluent limits. In some cases, even existing limits are met only with difficulty. Improved technology is needed to further improve performance of effluent treatment to meet the more demanding permits such as the Colorado Dept. of Health's permit for the COTTER CORPORATION's Schwarzwalder minewater which required 0.005 ppm Cu, 0.032 ppm Pb, and 0.05 ppm Zn. This also requires improved understanding of the practical limitations and process improvement possibilities that can be considered. Although the BEVILLE Amendment has temporarily suspended the applicability of the Federal RCRA rules on hazardous waste disposal to mine-mill wastes, several states are enacting their own solid waste disposal regulations which are as or more strict. There is still a significant gap between national objectives for fresh receiving waters and the levels that can be achieved in treated effluents. Litigation is also in progress in which the mineral processing industry is calling for a more lenient regulatory stance.

Performance of plants treating effluents for copper, lead, and zinc removal that were encountered in this investigation are summarized in the following table.

SUMMARY OF WATER TREATMENT PLANTS (mg/l)

Operation	Type	Effluent Treatment	Inflow	Outflow

CRITERIA FOR WATER TREATMENT SELECTION

Technology is one way to approach the water treatment problem to remove or recover unwanted copper, lead, zinc, and other contaminants. In all cases, the selection of such technology must be on the basis of the following criteria:

- It must be appropriate for the scale of operation contemplated.
- The technology must be appropriate for the concentrations of metals in the feedwater that is to be treated and must be capable of meeting the effluent requirement that must be met.
- The technology must be compatible with other contaminant removal processes that may have to be integrated into the system.
- The technology should not add other unwanted contaminants which do not meet effluent discharge limits or which would cause metallurgical interference if the product water is recycled to the mine or mill.
- Optimum performance must take into account not only solubility aspects, but also precipitate removal efficiency and disposal thereof.
- The process must be affordable and safe to operate.

The second approach to solving effluent treatment problems and reducing costs is through prevention. This means reducing the volume of effluent generated in the first place either through reducing drainage into the site, segregation of water on the site and cascaded use, etc., or reducing the opportunities for contaminants to get into the water in the first place and, finally, making more provision for water recycling. Some extremely innovative, yet simple, ideas have been encountered in this respect.

The following is a list of phenomena of interest and potentially useful observations on a variety of technologies that have been applied for treatment of effluents and/or process waters containing copper, lead, and zinc. Several phenomena have an important impact on technology selection and implementation from a practical chemistry point of view:

1. Hydroxide precipitation can be achieved by lime addition or through use of more expensive sodium hydroxide or soda ash. For precipitation to be effective, complexing agents must first be removed. Different complexing agents have different effects on each metal's solubility.

2. Next, each metal has an optimum pH at which its solubility is a minimum and, above which, the solubility of the hydroxide increases. For example, above pH 10.5, zinc

solubility increases due to formation of $[Zn(OH)_3]^-$. Since more than one of these metals are usually removed together, the optimum pH for removal of one of them may not be the optimum for the other metals that must be removed.

3. Co-precipitaion effects, particularly with iron, e.g., by $Fe_2(SO_4)_3$ or $FeSO_4$ addition often enhances removal of these metals when precipitation by OH^- addition is used.

4. After precipitation, the removal of metal values from solution to meet regulatory limits may not be possible by straightforward settling (decanting) due to difficult-to-settle precipitates. In such cases, more sophisticated clarification methods may be called for--possibly in conjunction with more sophisticated precipitation techniques, some of which are already in use in the mining industry.

5. Sulfides of copper, lead, and zinc are less soluble than hydroxides over a broader pH range even extending in the acid region.

Note.—Plotted data for metal sulfides based on experimental data listed in Seidell's solubilities.

SOURCE: Solubilities for metal hydroxides are taken from curves by Freedman and Shannon, "Modern Alkaline Cooling Water Treatment," in *Industrial Water Engineering* (p. 31), Jan.-Feb. 1973.

6. When employing hydroxide precipitation, complexing agents may compete to keep metals in solution. These are usually not strong enough to compete with sulfide precipitation, however. Complexing agents are not the same for each of the three metals. For example, the following table shows complexing cations which are known to interfere with hydroxide precipitation:

Metal	Complexing Agent
Copper	Cyanide CN^-, Ammonia NH_3, Humic Acids.
Lead	Humic Acid, Ammonia.
Zinc	Chromate $CrO_4^=$, Dichromate $Cr_2O_7^=$, Cyanide CN^-, Hydroxide above pH 10.5, Humic Acid.

7. Disadvantages of lime precipitation have been cited as:

- High lime costs.
- The need for pH adjustment.
- High volume of precipitate sludge produced especially if $SO_4^=$ ions are present.
- Low value of metals in the sludge rendering it less attractive for metal recovery and more expensive to dispose of.

8. At Jabiluka Uranium, Northern Territory, Australia, LEVINS (1979) reported levels of 15-100 ppm Cu in decanted effluent including raffinate from acidic uranium leaching operations in the Alligator Rivers Region of Northern Territories. After adjustment to pH 8 with lime, copper was precipitated to 0.3 mg/l. The acid solution contained 2-5,000 mg/l Fe which, no doubt, aided in the Cu removal by co-precipitation effects.

9. A summary of treatment processes for effluents from mainly metal finishing operations as presented by PATTERSON (1975) is presented below showing that even for these small-scale water treatment operations, levels below 0.3-0.5 ppm Cu are seldom achieved except by special processes.

Summary of Effluent Copper Concentrations after Precipitation Treatment.

Source and Treatment	Initial Copper conc. (mg/l)	Final Copper conc. (mg/l)	Reference
Metal Processing (Lime)	204-385	0.5	29
Nonferrous Metal Processing (Lime)	—	0.2-2.3 (prior to sand filtration)	30,31
Metal Processing (Lime)	—	1.6-7.8 (prior to sand filtration) 0.0-0.5 (after sand filtration)	32
Electroplating (caustic, Soda Ash + Hydrazine)	6.0-15.5	0.09-0.25 (sol.) 0.30-0.45 (tot.)	33
Machine Plating (Lime + coagulant)	—	2.2	34
Metal Finishing (Lime)	—	0-1.2 (ave. 0.19)	35
Brass Mill (Lime)	10-20	1-2	17
Plating	—	0.02-0.2	36
Plating (CN oxidation, Cr reduction, neutralization)	11.4	2.0	37
Wood Preserving (Lime)	0.25-1.1 (range)	0.1-0.35	38
Brass Mill (Hydrazine + NaOH)	75-124	0.25-0.85	16
Silver Plating (CN oxidation, Lime, FeCl,	30 (ave.)	0.16-0.3 (with sand filtration)	13

10. Copper as cupric oxide forms from the hydroxide which has a minimum solubility between pH 9.0-10.3 of 0.01 mg/l Cu. Fred Stevens of Lancy International, Zelienople, Pennsylvania, pointed out that at 43°C', copper precipitates as CuO rather than $Cu(OH)_2$. Copper oxide is much less soluble than $Cu(OH)_2$.

11. Copper as cupric can seldom be removed by hydroxide (lime) additions to its theoretical solubility because of poor separation of colloidal precipitates, slow reaction ratio, pH fluctuations, and the interference of other ions in solution. PATTERSON (1975) compared results of several metal finishing effluent treatment plants and found that hydroxide precipitation yielded effluents of 0.1-7.8 ppm Cu without filtration and 0.16-0.5 ppm with filtration.

12. Cuprous oxide forms a very dense easy-to-settle and easy-to-handle sludge of 40-60% solids according to the VOLCO BRASS CO. (1971), CROWLE (1971), and JACKSON (1972).

Treatment of cupric wastewater with hydrazine or some other reducing agent plus sodium hydroxide reduces copper to cuprous form and is recommended by several

authors for the treatment of metal finishing effluents, VOLCO (1971), CROWLE (1971), JACKSON (1972), and CURRY (1972). Surely the same would be achieved more easily with SO_2?

According to VOLCO (1971), such a system can be operated at pH 7-8, and a full-scale system has been reported in operation using the "integrated treatment" method in which copper was removed from a brass mill effluent by hydrazine and NaOH addition from 75-124 mg/l to 0.25-0.85 ppm.

In a second metal finishing application described by MARTIN (1973), the addition of caustic and soda ash to pH 9.5-10.5 with 300-700 mg/l hydrazine resulted in copper reduction from 6-16 ppm to 0.09-0.25 ppm soluble copper and 0.30-0.45 ppm total copper.

13. MURUYAMA, et al. (1972) studied copper removal from municipal wastewater enriched to 5.0 mg/l copper. Various combinations of lime and ferrous sulfate addition were examined for treatment effectiveness in a 4 gpm pilot plant. After chemical addition, flocculation, and settling, the effluent was sand filtered and passed through activated carbon columns. Compositions of the treated effluent are summarized in the following table as presented by PATTERSON (1975). It is noteworthy that the best removal of copper occurred at pH 6.0 with the addition of ferrous sulfate only rather than at higher pH with lime neutralization. Could the ferrous iron possibly be reducing cupric to cuprous resulting in improved removal of copper as cuprous oxide?

Treatment of Copper Wastewater

Process	Chemical Addition	pH	Effluent Copper (mg/l) (carbon column
Iron Only	43 mg/l $FeSO_4$	6.0	0.155
Low Lime	260 mg/l $Ca(OH)_2$, 20 mg/l $FeSO_4$	10.0	0.170
High Lime	800 mg/l $Ca(OH)_2$	11.5	0.352

14. BOLIDEN has observed unexpectedly low Cu/thiosulfate ratios in their tailing pond effluents, and it was speculated that copper may be reduced by thiosulfate from cupric to copper metal thereby removing it from solution. The above evidence of precipitaion of very insoluble cuprous oxide now offers an alternative.

15. In the treatment of gold mill effluents, e.g., barren bleed or tailings pond decant solution which contains copper that is complexed by cyanide, several methods of cyanide detoxification have been developed which also remove copper as a precipitate, e.g.:

Alkaline Chlorination	Giant Yellowknife	See Appendix I
INCO SO_2-Air	Scottie Gold Mine	DEVUYST, et al. (1984)
$FeSO_4 + Na_2S$	Cominco Con Mine	Appendix I
Bacterial	Homestake Mining Co., Lead, SD	Appendix I, MUDDER and WHITLOCK (1984)

16. Since copper is toxic to algae and some bacteria, caution should be used when considering the use of biological processes for copper removal, e.g., algae in meander systems for polishing or where bacterial removal of cyanide and copper is contemplated in the presence of high levels of copper. Nevertheless, low levels of copper, in the order of 0.15-1.5 ppm appear to be successfully reduced to ppb levels in the HOMESTAKE biological process for cyanide removal using rotating biological contactors. See the trip report on HOMESTAKE MINING COMPANY, Lead, South Dakota, in Appendix I.

17. Most of the objections to lime precipitation can be overcome when using the high density sludge process which is described in Chapter 24 on acid mine drainage treatment. The Bethlehem Mines Panther Valley Operation, one of many where the BETHLEHEM STEEL CORP. employs the HDS process, and COMINCO's application of HDS at Kimberly and Brail, B.C., are described. Further descriptions are included in Appendix I trips reports on:

    NORANDA MINES, Waite-Amulet
    Cu-Pb-Zn Mine-Mill G
    KROMDRAAI Coal Operation, South Africa
    ERPM, RAND MINES LTD., South Africa

    The principle of HDS is to recycle thickener underflow sludge consisting of precipitated metal hydroxides which is first mixed with lime before being added to feedwater to the plant.

    Examples of base metal removal in the course of HDS treatment are:

		Influent	Treated Effluent
NORANDA, Waite-Amulet	Cu	5-15 mg/l	LT 0.02
	Pb	-	-
	Zn	40-85 mg/l	0.20
	Cd	0.05-0.20	LT 0.005

COPPER-LEAD-ZINC

			Influent	Treated Effluent
Mine-Mill M	Ontario	Cu	LT 0.01	LT 0.01
		Pb	0.06	0.02
		Zn	3.14	0.1-0.3
NORANDA, Les Mines Gallen, Quebec		Cu	0.26	0.039
		Pb	-	0.160
		Zn	530	0.45
COMINCO, Kimberly, BC		Cu	0.15	LT 0.05
		Pb	5.0	LT 0.01
		Zn	22	LT 0.20

Major advantage of the HDS process is that the sludge generated has a high solids content, up to 40-50% if desired. It is therefore compact and more easily disposed of. In addition, BETHLEHEM INTERNATIONAL ENGINEERING CORP. has developed a way of mixing the sludge with a pozzolon to yield a stable waste material that passes the EP toxicity test (U.S. EPA, 1978) and is suitable for disposal in sanitary landfill sites. Secondly, metals are precipitated to lower levels from solution by the HDS process to form a non-amphoteric precipitate. Precipitation to low levels, usually less than 0.01 mg/l Pb and Cu, occurs at lower pH values than the optimum pH for conventional lime precipitation.

More details on this very powerful metal precipitation process are obtainable from:

Fe	2-26	>99
Fluoride	0	70-78

gold recovery effluent from 20 mg/l to below the detection limit by sulfide precipitation. They also found that similar results were attainable by co-precipitation with alum.

LARSEN, et al. (1973) used a two-step lime addition to pH 5 to precipitate iron and aluminum and then barium sulfide addition at pH 6.5 to precipitate heavy metals. Copper was reduced from initial levels of 50-115 mg/l to below 0.5 mg/l. LARSEN and ROSS (1976) described the same process, now called the DRI process, which was tested for treatment of acid mine drainage for the removal of Fe, Al, Cu, Pb, Zn, Hg, and Cd in Colorado. Attempts to locate the authors who were employed at the Denver Research Institute when the work was carried out were unsuccessful.

22. Sulfide precipitation processes are used to treat effluents from the large copper smelter and metallurgical works of BOLIDEN at Skellefteå, Sweden. BLYTHE, et al. (1981) described the operation and performance of the sulfide precipitation process at BOLIDEN which is complicated by the need to remove arsenic, which requires a two-stage process as arsenic sulfide is precipitated only at low pH. Results of the BOLIDEN installation are summarized in the following diagram from which it can be seen that:

- Copper is precipitated as a sulfide along with arsenic at pH 3.8. Lead is also precipitated but not as quantatively and, at the low pH, zinc is poorly removed.

- The addition of lime and settling drops zinc and lead to below 0.1 mg/l and 0.05 mg/l respectively.

It is clear that sulfide precipitation is very effective for base metal removal. Additional information is available from:

(606) 257-2798

23. MIKHNEV, et al. (1978) described the use of a solution of sulfide in $Ca(OH)_2$ to precipitate heavy metals from metallurgical plant effluents. The Cu, Ni, and Fe were precipitated at pH 5.2, 7, and 7-9 respectively. The degree of removal depended little on temperature in the range 20-80°C. The treatment at final pH 7.5-8 decreased the metal values in solution as follows:

	Cu	Pb	Zn
			COPPER-LEAD-ZINC
Before Treatment (mg/l)	70	80	10
After Lime-Sulfide (mg/l)	0.10	0.01	0.01

The precipitate contained Cu at 12%, Ni at 12%, and CaO at 20% as NiS, CuS, and $CaSO_4$ $2H_2O$, as well as S. Significally, the use of $Ca(OH)_2$-S solution in the place of $Ca(OH)_2$ increased the clarification rate by 50-100%.

24. It is rumored that the GENERAL ELECTRIC R & D GROUP has patented a process for metals precipitation which uses a combination of lime and sulfide.

Information has been requested from:

GE RESEARCH & DEVELOPMENT CENTER
Post Office Box 8
Schenectady, NY 12301
(518) 385-8247

A similar process employing calcium polysulfide precipitation and two stages of precipitation and filtration has been described by Italian workers COCHECI, et al. (1983).

25. The latest regulations for primary zinc refineries in the U.S.A. specify levels that will necessitate the use of Na_2S precipitation unless the AMC litigation against the EPA is successful in reversing the regulation. Most U.S. zinc smelters have looked into sulfide precipitation and have probably conducted some experiments which form the basis for their objections to the requirement that sulfide precipitation be used.

One of the major arguments may be that in generating a sulfide precipitate of base metals, a hazardous waste is generated that requires special disposal arrangements.

One of these companies with whom industry may be able to discuss the merits of sulfide precipitation is:

ST. JOE MINERALS CORPORATION

26. According to BHATTACHARYYA (1985 personal communication), one of the problems of the low pH sulfide precipitation is excessive cost of Na_2S reagent when sulfite

$SO_3^=$ is present and the efficient removal of metal sulfides by settling and filtration. Especially, copper forms a very finely divided sulfide precipitate which is difficult to remove. Another problem mentioned is the less effective removal of metals that form weaker sulfides when chelating agents or complexing agents such as cyanide are present.

Additional discussion of sulfide precipitation for copper removal is included in the following references:

LANTZ (1979)
U.S. EPA (1980, April)
U.S. EPA (1980, June)
BHATTACHARYYA, et al. (1979)
BHATTACHARYYA, et al. (1978)
LARSEN, H.P. and ROSS, L.W. (1976)
SCHLAUCH and EPSTEIN (1979)
ROBINSON and SUM (1980)
YELIGAR, et al. (1981)
SCOTT, M.C. (1979)

One of the most innovative aspects of sulfide precipitation is the PERMUTIT COMPANY's patented SULFEX process which employs a sludge blanket type clarifier with a sludge blanket of freshly prepared FeS which offers several advantages in the sulfide precipitation of metals. SCOTT (1979) reports that the SULFEX process can reduce copper from solution to below 0.01 ppm and zinc to below 0.05 ppm. Although the sulfide precipitate generated using the SULFEX process is reported by SCOTT (1979) to pass the EPA (1978) leach test, questions remain as to the long-term stability of the precipitates in landfill conditions where they may be subject to bacterial attack.

Although there is no record of the SULFEX process having been used for mine-mill effluents, the process appears to have considerable merit. More information can be obtained from:

THE PERMUTIT COMPANY, INC.
Post Office Box 355
Paramus, NJ 07652
(201) 967-6000

27. A variation on the SULFEX process which, however, does not employ the blanket type clarifier to contact solution with FeS is COMINCO's patented process for cyanide detoxification in which freshly generated FeS is employed to precipitate cyanide and also to precipitate heavy metals from the effluent of gold ore cyanidation. The

process is employed at the CON MINE at Yellowknife, Northwest Territories, and is described in a trip report in Appendix I. A copy of the U.S. Patent is included in the chapter on cyanide detoxification (KUIT and BABCOCK, 1981). SCOTT (1984) reported that copper was reduced from 50 mg/l to 0.3 mg/l and zinc from 155 to 0.04 mg/l by their treatment process which is pH dependent and, in this case, perates at pH 7.5.

28. PATTERSON (1975) mentions evaporative recovery as a means of treating copper bearing effluents containing 100-500 mg/l Cu. The copper residue has an economic value if it can be recycled or sold. This process does not appear to be economically attractive in the levels found in mine and mineral processing effluents.

29. Ion Exchange

Ion exchange is capable of achieving very high levels of copper removal, particularly from dilute wastes. Copper removal by ion exchange from 1.02 mg/l to less than 0.03 mg/l has been reported by BOTHAM and BRYSON (1953). The initial cost of an ion exchange system depends on the required resin volume. For dilute wastes, flow rate will be the limiting factor while resin exchange capacity dictates the volume for more concentrated systems.

PATTERSON (1975) points out that to be cost effective compared with other treatment processes, the copper values must be recovered. This also implies that ion exchange will be more favorable where the copper concentration in the effluent is relatively high--i.e., more usable copper to recover.

30. CHEM. ENG. (1971) describes the treatment of copper rinse solutions containing 70 mg/l ammonia. A selective ion exchange resin (Amberlite 1R120, Rohm and Haas) reduced copper from 45 mg/l to undetectable levels. Ammonia was dropped from 70 mg/l to 1 mg/l.

More information on further commercial developments for selective copper removal from low pH effluent solutions is likely to be available from manufacturers of the innovative ion exchange resins such as:

NADEN and WILLEY (?) reviewed solid ion exchange as a means of reducing the cost of copper recovery. David Naden is employed at:

DAVY McKEE LTD.
Bowesfield Lane
Stockton on Tees
England TS18 3HA
(0642) 67108

He pointed out the problem of poor Fe^{+++}/Cu^{++} selectivity of aminodiacetic acid resins which would require the scrubbing of ferric ions or removal by converting ferric to ferrous with SO_2. A table showing properties of commercially available resin types from his paper follows:

Commercially Available Resin Types

Resin Type	Name	Copper Adsorption pH	Fe Adsorption pH	Ca.Mg.Al Adsorption pH
1. Strong Acid (Sulphonic Acid)		0-14	0-14	0-14
2. Weak Acid (Carboxylic Acid)		>3.5	>3.5 Cu^{2+} Replaces Fe^{2+}	>5
3. Weak Base		~4	Fe^{2+} Not Absorbed; Fe^{3+} >1.5	Not absorbed
4. Strong Chelating Amido Diaceticacid	Rohm & Haas XE318 Dowex XFS 4132 Lewatit TP207 Dowex A1 Zerolit S1006	>1.5, Cu^{2+} & Fe^{3+}	>3.0	>6
Phosphonic Acid	Duolite ES63	>1	>1 Fe^{2+} & Fe^{3+}	absorbed
Amidoxime	Duolite CS346	>3.0	>1.5 Fe^{2+} & Fe^{3+}	Not absorbed
5. Inorganic Gels Zirconium Phosphate		1.0 - 1.5	Fe^{2+} >1.5; Fe^{3+} 1-1.5	Al^{3+} >1.5
Zirconium Phosphate Selectivity	$\frac{Cu}{Fe^{3+}} = 3.8$ $\frac{Cu}{Fe^{2+}} = 11$ $\frac{Cu}{Al^{3+}} = 12$			

Copper-Selective Ion-Exchange Resin with Improved Iron Rejection

Robert R. Grinstead
Dow Chemical U.S.A.
Western Division Research & Development Laboratories
Walnut Creek, Calif.

A new chelating ion-exchange resin with lower affinity for iron improves the efficiency of copper leaching. The resin is readily regenerated with dilute sulfuric acid or ammonia.

The properties of two chelating ion-exchange resins, FS 4195 and XFS 4196, which are selective for pper over most of the commonly encountered metal ns,[1,2] particularly ferric iron, have been reported eviously. The characteristics of XFS 4196 were de-ned for use in the processing of copper leaches to ectrowinning cell feed, in that regeneration can be complished with dilute sulfuric acid.

This paper will describe a new resin, designated FS 43084, which exhibits an increase of several fold copper/iron (III) selectivity, while retaining the er absorption characteristics of the original XFS 96. The basic characteristics of XFS 43084, in-uding distribution equilibria of a number of other etal ions besides copper and iron, and some kinetic ta, will be reported here. Performance in column plications will be described in a second paper[3].

EXPERIMENTAL METHODS

Equilibrium data for metal-ion absorption, were determined by uilibrating resin and solution for at least 16 hr., a time which s shown to be more than adequate for equilibrium to be achieved. e resin was eluted, either with dilute sulfuric acid or ammonium droxide, and both aqueous phases were analyzed by atomic-sorption spectrometry.

Resin loading data, unless otherwise stated, are expressed on the sis of the wet settled volume of the acid form of the resin, which s arbitrarily defined as the form in equilibrium with 0.1 N sul-ric acid. In some cases, volumes of resin were measured for ex-riments; in others, air-dried resin was prepared and measured by weight. In the latter cases, data were converted to a volume basis by use of the appropriate density and moisture contents.

In some cases, a value of the maximum copper capacity has been used. This value was determined by equilibration of resin with a copper sulfate solution containing 10 g Cu/l at its natural pH. The value so obtained is usually somewhat less than calculated by assuming one copper to be chelated per amine group. A major reason for this is the fact that 10-15% of the amines contain quaternized nitrogen atoms, which destroys their chelation ability.

GENERAL PROPERTIES OF XFS 43084

Table I gives some basic physical and chemical properties of XFS 43084. Data for XFS 4196 are given for comparison. Capacity properties of the two resins are similar. XFS 43084 does exhibit a somewhat lower water content and a smaller volume change from acid to base forms. It also exhibits a slightly lower apparent pK_a, as will be shown.

The general structure of resins of this type has been described in patents which were recently issued[4,5] and is based on picolylamine (2-aminomethylpyridine). The resins are macroporous polystyrene/divinylbenzene copolymers to which has been attached a chelating functional group. The structures of the active groups in the two resins are:

XFS 4196
N-(2-hydroxyethyl)-picolylamine
HEPA

XFS 43084
N-(2-hydroxypropyl)-picolylamine
HPPA

Absorbed copper ions are presumably coordinated not only to the two nitrogen atoms of the structure, but also to the oxygen of the hydroxyl group. Evidence for the participation of the hydroxyl exists in the fact that in acid solutions of the monomeric chelators, HEPA is a stronger chelating agent for copper than the unsubstituted picolylamine by a factor of about six[7].

BASE STRENGTHS OF THE RESINS

Because the functional groups are amines and have basic properties, the resins will exist in a protonated or salt form in contact with acid solutions, and in a neutral or free base form in alkaline solutions. Both the resin volume and its kinetic performance depend on the form of the resin, and it is important to determine the pH

Figure 1. Titration curves of resins.

Figure 2. Distribution of copper at pH 2.

range over which this transformation occurs. This is done by acid titration of the free base form of the resin, data for which are shown in Figure 1. Because of the slow achievement of equilibrium, each point represents a separate experiment, which was equilibrated for 16 hrs. The amount of acid actually taken up by the resin was determined by subtracting the acid remaining in the external solution from the total acid added to the system.

Protonation of both resins is clearly indicated by a buffer region with pK_a's in the region of pH 4-5, culminating in definite though imprecise endpoints in the general region predicted by nitrogen analyses of the resins. These points (shown by arrows) represent the total exchange capacity, as determined by nitrogen analyses, reduced by the amount of strong base capacity (quaternized amine). Lack of precise agreement is probably due mainly to impurities in the original chelating agent used to make the resin. Agreement is, however, sufficient to characterize the protonation reaction as involving one proton per functional group in the pH region above about 2.5 to 3. Below pH 2, further protonation occurs, but it is not possible to distinguish between two possible mechanisms: (1) protonation of the pyridine ring nitrogen; and (2) protonation of sulfate ion to bisulfate. It is likely that both are occurring, since more than one additional proton appear to be taken up in this region.

A volume change of the resin also occurs during the protonation. After the endpoint region is reached, in the vicinity of pH 3, no further volume change is observed, at least out to the end of the titration curve shown.

ABSORPTION EQUILIBRIA OF COPPER AND IRON

Since in copper leaches the most troublesome impurity is ferric iron, and since the absorption of these two species is somewhat interrelated, it is useful to examine their behavior together. Several variables are important, in particular pH and concentration of the metal ions. The distribution of cupric ion between sulfate solutions and XFS 43084 is shown in Figure 2 for three pH values in the normal range of leach solutions. Comparable data for the pH 2 series for XFS 4196 are also shown for comparison, and are quite similar.

Distribution of ferric iron for XFS 43084 is shown in Figure 3. In the absence of copper, the iron loads readily up to a level of about 22 g Fe/l (about 0.4 moles/l, which is about half of the total ion exchange capacity of the resin. If iron were absorbed by a chelate mechanism, one would conclude that one iron is being shared between two chelating groups. We believe, however, that iron is absorbed by an anion exchange mechanism involving the sulfate anion, presumably in the same way as occurs with non-chelating, strong-base anion exchange resins.

The second curve was obtained in the presence of a fixed amount of copper, giving the resin loadings (in g Cu/l) shown by the numerals at each point. Aqueous equilibrium copper concentrations were all 0.7 ± 0.05 g Cu/l.

The effect of iron on copper loading is rather minimal and is in fact undetectable below about 4 g Fe/l. The effect of copper on iron absorption in this range, however, is quite marked, causing a reduction in iron distribution coefficient of 4-5 fold.

Figure 3. Distribution of iron (III) at pH 2.

Figure 4. Effect of copper loading on iron (III) absorption.

effect of copper is shown in a different manner in Figure 4, the distribution coefficient of iron is plotted as a function per resin loading. The data for XFS 4196 are shown for com-n, and the higher selectivity of XFS 43084 is clearly evident, ting to about fourfold at typical copper loading levels. The selectivity, if defined as the ratio of distribution coefficients er/iron) is about 30 for XFS 43084 in the range of resin load-t 30 g Cu/l, as compared to about 8 for XFS 4196. This selectivity provides a double advantage for rejecting iron: only about one-fourth as much iron will load on a copper-g resin; second, the reduced distribution tendency of iron any type of a scrubbing operation more effective by the same

bably the most important variable governing metal ion ab-on is pH. The source of this dependence lies, of course, in the basicity of the resins. In its simplest form, the absorption of al ion by the resin can be expressed as follows:

$$M^{+m} + \overline{R \cdot nH^+} \rightarrow \overline{MR^{+m}} + nH^+ \;;$$

$$K' = \frac{(\overline{MR^{+m}})\,(H^+)^n}{(\overline{R \cdot nH^+})\,(M^{+m})} \qquad (1)$$

R represents the resin structure, and barred species are in sin phase. This is obviously not a complete expression of the ption process, since if m≠n, then some sulfate species must er into or out of the resin to maintain electrical neutrality. ch a situation, K' will, strictly speaking, not be a constant, ill depend upon the sulfate concentrations in both the resin olution phases. However, if one works in systems where the e concentration does not change appreciably, K' will be constant.

shall define the Conditional Absorption Constant, K, by llowing expression:

$$K = \frac{K'}{(H^+)^n} = \frac{(\overline{MR^{+m}})}{(\overline{R \cdot nH^+})\,(M^{+m})} \qquad (2)$$

thus a parameter which depends upon pH, and can be used strate the dependency of metal ion absorption as a function this expression, the quantities containing the metal ion ermined by analysis. Determination of the unused resin es a knowledge of the total capacity, which is obtained from tion loading experiments.

Figure 5 are shown plots of K for both copper and iron (III) unction of pH. The direct dependence of copper absorption on nforms to that predicted by the equation, although the depen-is somewhat greater than first power over most of the range. is presumably due to the fact that in this range (mainly pH 2), more than one proton exists in the unloaded resin. The for XFS 43084 and XFS 4196 are quite comparable, as was n earlier in Figure 2.

e iron data for the two resins appear nearly identical, in con-to the behavior depicted in Figure 4. The identity is more ent than real, since the curves in Figure 5 at pH 2 are sepa-by a factor of about 2, with the XFS 43084 exhibiting the iron absorption. This is about the same factor observed in e 4 at the zero-copper point.

KINETICS OF EXCHANGE

hough equilibria are of fundamental importance in characteriz-resin, the rate at which equilibrium is achieved is at least as tant, perhaps more so, from a practical point of view. Kinetic rmance can be measured in a variety of ways, but because of omplexity of ion exchange equipment, it is difficult to relate e laboratory kinetic data to column performance. It is possible, er, to observe qualitatively some important aspects of kinetics tal exchange.

e important aspect is the difference between kinetics of ab-on by the acid and base forms of the resin. It is well known water-treating technology that weak-acid and weak-base are relatively slow when used in their un-ionized forms. characteristic is usually ascribed to the fact that in these lack of a charged species reduces the affinity of the resin , which results in a smaller volume of the un-ionized form correspondingly restricted space through which exchanging s can diffuse. This effect was observed for XFS 43084 by ng out batch contacts with copper and iron solutions, monitor-he concentration in the aqueous phase, and calculating the

	4.0	1.13	2.1	3.1

*Resin: solution volume ratio = 1.2/100; initial aqueous concentrations, 1g/l metal except Ca, which was 0.2 g/l

resin loading by difference. Data for these experiments are shown in Figure 6 for absorption and Figure 7 for elution of copper.

Two points deserve mention. First, the rate of copper absorption is much faster for the acid form of the resin. If the half-times (i.e., the time to reach half of the equilibrium loading) are compared, the acid form is over four times as fast as the base form. The second point is that iron absorption is somewhat faster than copper under the same conditions (about 18 minutes vs. about 22 minutes for copper).

Elution of copper by 2N sulfuric acid, a typical eluant, is much more rapid than absorption, as Figure 7 shows. A half time was found to be about 1.5 minutes, some 15 times faster than for absorption. The greater exchange rate is probably mainly the result of the relatively high acid concentration.

Although not studied in detail here, copper can also be readily eluted from XFS 43084 with aqueous ammonia, just as with XFS 4196. This provides an additional flexibility in terms of the form of the final concentrate which can be obtained.

ABSORPTION OF OTHER METALS

Typical equilibrium absorption data for XFS 43084 are given in Table II for several common metals of potential interest in metallurgical operations. Additional data are shown in Figure 8 for most of these metal ions. In all cases the curves exhibit the typical rise in the value of K through the region in which the resin protons are ionizing, reaching a plateau at high pH. Of the metal ions commonly encountered in copper dump leaches only copper and ferric iron exhibit appreciable absorption below pH2. Certain anionic species can be absorbed, however, as was reported earlier. Besides ferric iron, which is mainly absorbed via an anion exchange mechanism, uranyl ion is also absorbed, as well as species such as molybdate, chromate, and vanadate(1).

ABOUT THE AUTHOR

Robert R. Grinstead is an Associate Scientist in the Western Division Research Department of Dow Chemical U.S.A. He graduated in chemistry from University of California at Berkeley in 1946, and obtained his PhD in Chemistry from the California Institute of Technology in 1950. He joined Dow at that time, participating in the development of the solvent-extraction and ion-exchange processes now used in the uranium industry. His interests since then have included mechanisms of model enzyme redox systems, the recovery of minerals and metals from brines and other raw materials sources, waste water recycling, and air- and water pollution control processes. His current interests center primarily around applications of metal chelate chemistry, of which the chelate resins described here are a principal outgrowth. He is a member of the editorial board of the Journal *Hydrometallurgy*.

31. In 1984, a large solvent extraction plant was commissioned to recover copper values from minewater at the El Teniente Mine in Peru.

	Water Flow Rate	Copper Production
Minimum	250 m^3/h	Less than 1,000 tpa Cu
Nominal	612 m^3/h	4060 tpa Cu
Maximum	900 m^3/h	4611 tpa Cu

At nominal flow rates and less, the plant operates in a conventional counter current two-stage extraction and two-strip mode. For higher flowrates, the plant is connected with the two extraction units in parallel. This caters for the seasonal variation in flow and tenor of copper concentration which reputedly can rise as high as 2 g Cu/l. More information can be requested from the designers and constructors of this innovative plant:

32. Attempts have been made to regenerate gold and silver cyanidation barren bleed solutions by removing contaminating metals from the cyanide stream. No known commercial application of this process has been identified to date.

33. The COTTER CORPORATION at their Schwarzwalder Mine, Golden, Colorado, employs a highly innovative continuous plug flow ion exchange system to treat minewater as described by PALMER, et al. (1984).

Although designed primarily to remove uranium from 2-7 ppm to meet the effluent discharge regulation of 0.06 mg/l U_3O_8 max., the system also had to meet a 30-day average maximum 0.005 ppm Cu. Analyses of the feedwater effluent are compared with the Colorado Dept. of Health permit as reported by PALMER, et al. (1984).

	Feed mg/l	IX Effluent mg/l	Discharge Permit 30d Ave. (mg/l)
Uranium (dissolved)	2-7	LT 0.010	0.060
Cadmium	0.002	0.0004	0.0004
Copper	0.02	0.005	0.005

	Feed mg/l	IX Effluent mg/l	COPPER-LEAD-ZINC Discharge Permit 30d Ave. (mg/l)
Lead	-	0.005	0.032
Zinc	0.0026	0.05	0.05
Radium pCi/l	50-100	5	5
Sulfate	800	800	N.A.
Chloride	60	60	N.A.
Barium	-	1.0	1.0
Arsenic	-	0.050	0.050

The above results, which reduce copper and cadmium levels to 5 ppb and 0.4 ppb respectively were achieved using a 500 U.S. gpm continuous downflow ion exchange system with the following parameters:

Flow Rate:	500 U.S. gpm
Column Diameter:	4-7 Feet
Number of Stages:	Two Downflow Adsorption Stages in Series; One Downflow Elution Column
Resin Depth:	6-7 Feet
Column Height:	12 Feet
Elution:	13% H_2SO_4
Eluate:	12 g U_3O_8/l
Resins:	Dowex Rohm & Haas Anion Exchange Diamond Shamrock Duolite AIOID Anionic
Resin Loading:	To 35 g U_3O_8/l

More details are provided in the Appendix I trip report and in the PALMER, et al. (1984) paper. The innovative ion exchange system was designed and installed by:

34. PATTERSON (1975) referred to the innovative counter-current continuous regeneration system which yields high tenor eluates with 3-4 N copper. There are several similar counter-current systems for elution which can be considered. Some are upflow, and others are downflow. Some are fluid-bed while others are plug flow. Although not many have been used as yet for copper, lead, or zinc recovery, these systems as employed for low-grade uranium recovery could be considered if needed. RANDOL (1980) has provided details of all the major CIX (continuous ion exchange) systems available that could be considered for this purpose, although the RANDOL study was oriented toward uranium recovery.

35. Ion Exchange - Zinc Recovery

At METSEP (PTY) LTD., Germiston, South Africa, an ion exchange plant was installed in the mid-1970's to recover zinc from pickle liquor acid. Despite the relatively high tenor of the feed solution, this process was a technical success but an economic failure. The plant is owned by WOODALL DUCKHAM LTD., a U.K. company with South African partners.

36. Electrolytic Recovery

Direct electrolytic recovery of copper metal is said to be possible (PATTERSON, 1974) from relatively concentrated waste solutions. According to JACKSON (1972), treatment of dilute solutions (less than 2 g/l) using conventional electrolysis is impractical because of high power consumption. Normally, some form of preconcentration such as ion exchange is needed. SIMPSON and THOMPSON (1950) refer to direct electrowinning of copper from acid leach solution from an ore in which the regenerated sulfuric acid electrolyte is recycled. This application is applicable to concentrated solutions and would not be not applicable to typical mine and mineral processing solutions and effluents.

According to VOLCO BRASS (1971), the proper control of electrolysis current can eliminate the problem of other metals plating out. Again, this is an interesting phenomenon but applicable to concentrated metal finishing solutions.

PATTERSON (1975), SILMAN (1971), JACKSON (1972), and the AMERICAN ELECTROPLATING SOCIETY (1969) described a process which claimed to make electrolytic treatment of dilute copper cyanide solutions economically attractive. The process consists of a fluidized semi-conducting carbon bed across which a potential is applied. The large surface area per unit of volume, which provided a low-current

density on the electrode surfaces but a high current density across the cell, reduced the power consumption. The system was built for small-scale application for plate shops but never found commercial application in treating mine and/or mill effluents. ENVIRON. SCI. TECHNOLOGY (1970) carried an article in which it was claimed that 20 mg/l CN is reduced to 0.5 mg/l, and 40 mg/l is reduced to below 1.0 mg/l for roughly 5% of conventional treatment costs at about 100 times the rate of conventional electrolysis treating wastes of similar strength as inserted below.

RESOURCE CONTROL, INC. of West Haven, Connecticut, was shown in the article as the vendor, but in 1985 no record of this company in West Haven, Connecticut, or in any directory could be found.

37. During the early 1980's, the CANADA DEVELOPMENT CORP. financed development of an electrolytic equipment item for cyanide removal or recovery of metals from dilute effluent solutions. The basis of the development by HSA REACTORS LTD. was to use a very high surface area carbon fiber cathode. However, in 1984, HSA REACTORS LTD. was liquidated. The equipment had been tested on barren bleed regeneration from gold cyanidation operations at CAMPBELL RED LAKE MINES in Ontario. Again, this technology appears more appropriate for smaller flows associated with plating wastes than high volume mine and mill effluents.

38. Several universities continue to work on low-level metal removal by electrolysis, generally using high surface area electrodes or fluid bed electrodes of one form or another. One of these workers is:

PROFESSOR A. W. BRYSON
Dept. of Chemical Engineering
University of the Witwatersrand
Johannesburg 2001

It is noted in the table of Test Plant Results included in the paper by BRYSON and DARDIS (1980) inserted below that even with the high surface area electrode operating on a small demonstration scale, the effluents are still around 1 mg/l for Cu, Pb, and Zn--clearly not low enough to be of much use in meeting effluent requirements for the close of the 20th century.

Electrolysis speeds up waste treatment

New electrical process hastens destruction of contaminants in liquid plating wastes

A new wrinkle to the chemical industry's ancient art of electrolysis may provide those who have been seeking a cheap, simple means for treating dilute liquid wastes with just the technique they've been looking for. At least Stauffer Chemical Co.'s specialty chemicals division thinks so. The division has just reached an agreement which will give it exclusive rights to market a new electrolytic process developed by Resource Control, Inc. (West Haven, Conn.), to the metal finishing industry.

Stauffer, as a supplier of chemical products for the plating industry, had been looking for some time for an effective, low-cost way to treat dilute plating wastes, so that its customers in the industry would have a practical means for dealing with a growing water pollution problem. At the same time, Resource Control, Inc. (RCI), a relatively small company without a large marketing force, was seeking outlets for its new process which previously proved effective in treating plating wastes at several U.S. sites.

Waste problem

The metal processing and finishing industries produce large volumes of dilute wastes. These arise in the rinsing operations carried out to remove chemicals from metal parts. Since there may be as many as 15 separate steps in a finishing operation, a typical shop has numerous rinse water streams, each contaminated by different chemicals. Commonly, the chemical contaminants which must be removed before the water is discharged are cyanide, hexavalent chromium and heavy metals (silver, cadmium, zinc, copper, etc.).

The usual way of removing the contaminants is by chemical treatment: Cyanides are oxidized by sodium hydroxide and chlorine, the chromium cation is reduced by sulfur dioxide, and metal bearing wastes are chemically neutralized to precipitate the metal as an insoluble salt.

New twist

Although electrolysis has been used in the past to treat metal finishing wastes, it has been found to be a slow and costly method. Generally performed batchwise, the oxidation and reduction reactions necessarily have been slow because the electrical resistance of the waste is high, particularly when the concentration of contaminants becomes small and the liquid is ionized only slightly.

RCI has managed to overcome the problem of high resistance by using a cell in which the space between anode and cathode is packed with carbonaceous material. (The exact nature of the material is not being revealed, but RCI says that it is cheap enough to be discarded after several months of use, consists of small particles, and takes up only 50% of the available cell volume.)

Avery Smith, president of RCI, refers to the bed as semiconductive. For some reason, the presence of the particles does not short-circuit the anode and cathode, as might perhaps be expected. What does happen, or so RCI believes, is that each individual particle gains, at different parts of its surface, a positive and a negative charge. Oxidation and reduction of contaminants in the waste then take place at the anodic and cathodic sites on each particle. The result is that the amount of current flowing is essentially independent of the conductivity of the waste, and the chemical reactions which destroy the contaminants take place more quickly (more than 1000 times as fast, RCI claims) than in conventional electrolysis using the same applied voltage (typically, 12 volts d.c.). Power costs are cut, too.

The new system is capable of reducing the concentration of cyanide ion in a waste stream from 20 p.p.m. to less than 0.5 p.p.m. with a corresponding reduction in copper content (in the case of copper cyanide plating) from 40 p.p.m. to less than 1 p.p.m. Similar reductions in hexavalent chromium are claimed by the company, which also has calculated that the system costs 95% less to operate than conventional chemical treatment.

RCI presently is manufacturing mobile, easily installed units rated at either 5 or 10 gallons per minute. These sizes are deemed adequate for the average metal finishing shop, but larger units can be custom built, according to RCI. Capital outlay called for is less than $20,000 for the typical shop.

Applications

RCI's Smith is enthusiastic about the possible uses of his company's electrolytic technique for the treatment of a wide variety of liquid wastes—in fact, any waste where the contaminants are capable of being oxidized or reduced to a harmless or easily disposable form. Whether the method will find wide application, of course, remains to be seen, but, if its attractive economics in the metal finishing field can be taken as a guide, it certainly will be a competitor to better established waste treatment processes.

Neutralized. *Stripchart records pH of metal plating wastes after electrolysis*

Treatment of Dilute Metal Effluents in an Electrolytic Precipitator

A.W. BRYSON and K.A. DARDIS
Department of Chemical Engineering, University of the Witwatersrand, Jan Smuts Avenue, Johannesburg, 2001

Abstract

Excessive concentrations of metals in industrial effluents may adversely affect the performance of sewage purification works. Although there is existing technology for treating these effluents, it has not found wide application due to costly equipment and chemicals and the absence of sufficient space on most plants. In this paper the feasibility of removing these metals from dilute solutions by electrolytic precipitation using a particulate electrode is investigated.

Based on laboratory investigations a test plant was constructed which was compact, did not require the addition of chemicals and could be operated by unskilled personnel. The plant was installed at an electroplating works on the Witwatersrand and was extremely successful in treating wash waters containing copper, nickel chromium and zinc.

Introduction

The harmful effects of heavy metals on human and animal life have been known for a very long time: for instance, lead poisoning was probably first recognised by Hippocrates (370 BC) and mercurialism was described by Pliny (AD 29) in his writings on the diseases of slaves (Hunter, 1975). It is only in recent years, however, that public concern, spurred by such incidents as outbreaks since the early 1950's of minamata disease (the deformation of the foetus in the womb due to mercury absorbed by the mother), has led to the introduction of strict legislative standards governing exposure to heavy metals and the discharge of effluents containing these metals.

Such effluents are produced by a broad spectrum of sources which include the metal refining, metal plating, tanning, chlor-alkali, anodising and automotive industries. The wastes contain a wide range of metal ions including arsenic, antimony, cadmium, chromium, copper, lead, manganese, mercury, silver, selenium and zinc. Electroplating effluents can also contain additional quantities of extremely toxic cyanide compounds. The magnitude of the problem may be gauged by the fact that it is estimated that at least 10 000 tons of copper are discarded in electroplating rinse waters in the U.K. annually (Tseug and Mahmood, 1977) and in the United States the value of nickel and chromium lost in plating wastes, has been conservatively estimated at 50 60 million dollars per year (Cherry *et al.*, 1975). In 1973 losses of chromium and nickel in the Johannesburg municipal area alone were estimated to cost a quarter of a million rands (Funke and Coombs, 1973).

Toxic effects of metals have been observed at very low levels (Funke, 1973; Nemerow, 1971) and can pose problems during treatment in conventional sewage works where, above certain threshold concentrations, they can disasterously inhibit the bacterial action of the sludge digestion process. Even when the metal concentration of the raw sewage is low enough for efficient removal, the metals could still be concentrated to levels in excess of 1 000 mg/ℓ in the sludge discarded by the works and would make the sludge unacceptable as a nitrogenous fertiliser for crops or grazing (Coker and Davis, 1978).

Treatment Methods

Treatment of metal effluents is likely to be most effective at the source of the pollution where the concentration is highest. The conventional method consists of essentially three stages. The cyanide content is oxidised to nitrogen and sodium bicarbonate with sodium hypochlorite. Hexavalent chromium is reduced to the trivalent form using reagents such as ferrous sulphate, sodium metabisulphite or sulphur dioxide. Finally, neutralisation by addition of sodium hydroxide or lime for acid solutions or sulphuric acid for alkaline solutions, takes place. The metal hydroxide precipitates thus produced are then dewatered by settling or filtration. The resulting sludge (containing 10–50% solids) is dried and either dumped or incinerated.

Alternative treatment methods include ultrafiltration, reverse osmosis, electrodialysis, ion exchange, solvent extraction and cementation with scrap iron (Mantle, 1976). Other less well known methods which may be used are foam fractionation, complexing with polyelectrolytes and adsorption of organometallic complexes on activated carbon (Mulligan and Fox, 1976; Young, 1975).

The methods of metal removal considered above, while they might succeed in producing a treated effluent of sufficiently high quality, suffer from a common drawback, namely that it is generally difficult to recover the metal from the waste stream without further treatment. Electrolysis, on the other hand, has the proven capability of producing metal directly from effluents in a form suitable for recycling.

The conventional flat plate electrochemical cell has been used for many years for treating relatively concentrated solutions. Silver is routinely recovered in this way from photographic wastes (Nemerow, 1971), and in the electroplating industry such cells are used for the oxidation of cyanides and the regeneration of chromic acid (Kuhn, 1971). When the concentration of most metal ions is less than about two grams per litre, however, plating efficiency drops dramatically and unless the current density is progressively reduced, competing reactions eventually dominate.

The poor performance at low concentrations of conventional cells is due to mass transfer limitations. As the current density is increased, more and more reactant is consumed, until a point is reached where the concentration of the reactant at the electrode surface becomes zero. The rate of deposition then becomes limited by the rate of diffusion to the electrode and any further increase in current density or decrease in reactant concentration must result in some competing reaction (usually that of hydrogen evolution) becoming significant. The designer of a cell intended for operation at low concentrations must therefore either specify a very low current density (and consequently a

very high surface area) or must reduce the resistance to mass transfer by stirring or by some other means.

The particulate bed electrode cell, in which the conventional plate electrode is replaced by a three dimensional fixed or fluidised bed of conducting material satisfies both requirements (Pickett, 1979). The surface area per unit volume can be very large and mass transfer from the solution pumped through the bed is enhanced by the very nature of the cell construction. The cell current is supplied to the bed by a current feeder which may be either a backing plate or a wire grid inserted into the bed.

Experimental

Laboratory-scale fixed and fluidised-bed cells were tested with a variety of effluents. Although the fluidised-bed proved to be slightly more efficient in most cases it required fairly tight control on the flow-rate. This type of cell also had to be operated in a vertical position to obtain uniform fluidisation. The fixed-bed electrode did not suffer from either of the above restrictions and it was decided that this system would be preferable to use on a plant where there is a lack of skilled operating personnel. All subsequent work was restricted to the fixed-bed type of equipment.

Figure 1 shows diagrammatically the essential components of a cell and flow system which were designed specifically to reduce the concentration of nickel from 20 mg/ℓ to less than 2 mg/ℓ at a flow-rate of 180 ℓ/h and a current of 30 A. The dimensions of the packed sections were L = 1 900 mm, B = 350 mm and W = 5 mm. The packing consisted of crushed graphite which was sieved to a size range of 1,2 mm to 1,7 mm. The cell was tested on site at an electroplating works near Johannesburg where it was used to treat the wash water from various plating lines. The results are summarised in Table 1.

TABLE 1
TEST PLANT RESULTS

Solution Treated	Metal Removed	Concentrations (mg/l) Inlet	Outlet	Flowrate (l/h)	Current (A)	Voltage (V)	C.E. (%)
NCW	Ni	22,6	1,5	180	30	5,4	12
NCW	Cr	13,5	1,0	180	30	5,4	12*
ACW	Cu	57,5	0,9	360	40	5,0	28
ZCW	Zn	16,2	1,5	360	20	3,5	22

NCW = nickel and chromium wash
ACW = acid copper wash
ZCW = zinc cyanide wash
C.E. = overall current efficiency.
*The current efficiency for chromium is based on the reaction $Cr^{6+} + 3e \rightarrow Cr^{3+}$

Discussion and Conclusions

The results show that the test plant was able to achieve greater than 90% reduction in nickel concentration even though the effluent solution contained chromium as well. The plant also performed very well in treating copper and zinc effluents where it was possible to double the flow-rate while maintaining an acceptable outlet concentration.

It may thus be concluded that the electrolytic system proposed can be used to remove a variety of metals from dilute solutions in equipment which is compact and has a low operating cost in terms of power requirements. It also has the potential for economically recovering metals in re-saleable form. These aspects, however, have not yet been studied in detail and hence a comparison of costs with other treatment methods is not possible at present.

39. Cementation

Cementation of copper onto a bed of scrap iron is useful for recovery of copper from both concentrated and dilute effluent streams and has been described by DEAM, et al. (1972), HILL (1972), CIANCA (1972), JESTER and TAYLOR (1973), CASE (1974), ANDERSON and HOLLINGWORTH (1972), and JACKSON (1972). By oxidation-reduction reaction, copper cements onto the iron with sacrificial iron going into solution. PATTERSON (1975) refers to one plant in which copper averaging 80 mg/l (range 34-220 mg/l) was reduced to an average effluent of 0.33 mg/l (range 0.2-90.84 mg/l Cu). The copper can be recovered as essentially pure metal representing a significant offsetting savings to treatment costs.

40. FAULKNER (Undated) points out that the cost of cementation recovery of 1 lb. Cu depends on the amount of ferric iron in solution and the Fe^{3+}/Cu^{2+} ratio because ferric ions also consume iron scrap. He describes a process whereby, with the use of SO_2 and activated charcoal, the ferric ions can be inexpensively reduced to ferrous prior to contacting the scrap iron with the solution to be treated.

CONTROLLING IRON AND ACID COSTS IN THE PRODUCTION OF CEMENT COPPER WITH SULFUR DIOXIDE AND ACTIVATED CARBON

W. D. Faulkner

Familiarity with activated carbon in the metallurgical field started with its use to extract gold and silver from chloride, and later, cyanide solutions. In the mid '50s its use to remove molybdenum from acid uranium circuits became an established practice. As in the case of molybdenum and uranium, activated carbon can selectively adsorb metals from solution making it a useful tool in extractive metallurgy.

Activated carbon can also function as a catalyst. It is in this capacity that the copper industry, or more specifically, the phase of the industry dealing with leaching and cementation, is interested. The reaction of primary importance is the catalytic reduction of ferric iron in pregnant leach liquors by sulfur dioxide. The purpose of this paper is to present the practical and economic implications of using this approach to eliminating the detrimental effects of ferric iron. Before presenting details on the system, perhaps some background on activated carbon would be of interest.

Activated carbon differs from other forms of carbon such as coke, graphite, carbon black, etc., in its structure and internal surface area. X-ray studies have shown that activated carbons are composed of randomly dispersed graphitic-like crystallites of submicroscopic dimensions. Each crystallite is composed of a number of layers and each layer contains carbon atoms arranged in a pattern identical to that in a poly-nuclear aromatic compound. In the case of activated carbons the distance between the layers are greater than that for graphite. A structure of this kind leads to a very complex network of fine pores and consequently a very great internal surface area.

The total surface area of commercial carbons range from 600 to 1400 square meters per gram and have internal pore volumes ranging from 0.6 to 1.0 cc/g. This means that one pound of carbon can provide more than 100 acres of surface area.

Examples of established catalytic applications are the production of phosgene from carbon monoxide and chlorine and in the dechlorination water. It is also used to support the catalysts used in the manufacture of vinyl acetate and vinyl chloride monomers.

Our discussions here are pertinent to dump, heap, and vat leaching operations where cementation is used to extract copper values from solution. Since the tailings solutions after cementation are normally returned to the leaching areas because of water shortages or pollution considerations, the following discussions are presented with this in mind.

Theoretically 0.88 pounds of iron are required to precipitate 1.0 pounds of copper

$$CuSO_4 + Fe \rightarrow Cu + FeSO_4 \quad (1)$$

The actual iron consumption for most of the U. S. operations fall in the range of 1.3 to 2.8 lbs. Fe/lb. Cu. The presence of ferric iron in the pregnant solutions accounts for much of the excess iron by the reaction

$$Fe_2(SO_4)_3 + Fe \rightarrow 3FeSO_4 \quad (2)$$

This reaction proceeds at a much faster rate than reaction (1) and it is not possible to get a reasonable copper recovery before the ferric reduction is complete. Reaction (2) actually accounts for 5 to 50% of the total scrap consumption in the industry.

The attack of acid on the scrap constitutes another source of consumption by

$$H_2SO_4 + Fe \rightarrow H_2 + FeSO_4 \quad (3)$$

This reaction is much slower than reactions (1) and (2) but in most plant operations the reaction essentially goes to completion before the solutions exit from the precipitation section. More will be presented on this subject later.

To reduce one pound of ferric costs 1.38¢ assuming a scrap cost of $55/T. This may be a substantial cost depending upon the Fe^{+++}/Cu^{++} ratio in solution. Also, better than 95% of the iron dissolved during each cycle precipitates out in the dumps and is suspected of imparing leaching efficiency by blinding mineral surfaces.

A lower cost ferric reductant other than scrap iron would have a direct economic advantage and an indirect advantage of reducing the iron load in the recycled solutions. Although sulfur dioxide would be cheaper it does not react swiftly enough to be practical. With the aid of activated carbon it does. The reaction is as follows:

$$Fe_2(SO_4)_3 + 2H_2O + SO_2 \rightarrow 2FeSO_4 + 2H_2SO_4 \quad (4)$$

When an amount of SO_2 stoichiometric to the Fe^{+++} is added to the solution and passed through a column of activated carbon, the effluent contains no ferric iron and all of the SO_2 is consumed. The retention time in the carbon bed is a matter of minutes.

The SO_2 requirement is 0.57 lb./lb. Fe^{+++}. The source of SO_2 will establish the cost. Estimates of $15/T for SO_2 produced from pyrite and $28/T from elemental sulfur have been advanced. These correspond to reduction costs per pound of ferric of 0.44¢ and 0.80¢, respectively, versus the 1.38¢/lb. with scrap iron. Purchased liquid SO_2 is also a possibility.

You will note from reaction (4) that H_2SO_4 is one of the products. For each pound of ferric reduced, 1.75 lbs. of H_2SO_4 are generated.

The presence of this acid raises a question. Although ferric iron is being eliminated from the system, won't the advantage be negated by the attack of the generated acid on the scrap? If no control over solution residence time in the precipitation section is exercised, the answer is 'yes'. However with proper control, the effect can be minimal.

To show that this is possible, the following test was conducted. A synthetic pregnant solution of the following composition was prepared:

Ferric iron	10	g/l
Ferrous iron	40	g/l
Copper	3.1	g/l
H_2SO_4	17.5	g/l

The solution was divided into two lots. The first was used as prepared. Stoichiometric SO_2 was introduced into the second and passed through a bed of Pittsburgh Type SGL 8 X 30 mesh Activated Carbon. Both solutions were then contacted with iron filings and monitored for copper qualitatively. When the concentration of Cu^{++} became less than 0.1 g/l, the iron was removed. The iron consumption was 2.66 lb./lb. Cu for the "as prepared" solution. The reduced solution gave an iron factor of 1.16 lb. Fe/lb. Cu even though it contained 35.0 g/l H_2SO_4.

It should be emphasized that these results were obtained under laboratory conditions in which the iron was removed from the system as soon as cementation reaction was complete. Similar results in plant practice will require similar control.

The acid in the tailings solution has potential economic appeal, since many operations add acid before returning the solutions to the leaching areas.

In the precipitation section itself, the presence of acid should result in a faster rate of copper precipitation. Since the pH of the solutions would not rise to the 3.2 plus area, the cement product should be higher grade due to the absence of precipitated iron salts.

The efficiency of the activated carbon is a function of the pore structure, internal surface area, and mesh size. After evaluation of several carbons we have recommended Pittsburgh Type SGL in an 8 X 30 mesh range. Field tests to date show no loss in catalytic efficiency of Type SGL with time.

Solution temperature does influence the ferric and SO_2 reaction. A synthetic solution was prepared and divided into two lots. Stoichiometric SO_2 was added to both solutions and run through carbon beds at identical rates. The only difference was temperature. The ferric reduction was 91% complete at 25° C. but only 62% was reduced at 5° C. For 100% reduction, the maximum retention time in the carbon reactor under extreme conditions is 15 minutes. Generally, retention times of 5 to 10 minutes will give complete reduction.

Slimes are commonly present in the pregnant liquor. Since such large solution flows are involved, filtration would be expensive. Granular carbon is an efficient filter media for suspended solids in packed beds. If the carbon reactor is operated downflow, then a backwash to remove solids would be required periodically.

We feel the practical approach to the slimes problem is to operate the system upflow with the carbon free to expand. A high density carbon will permit a solution linear velocity sufficient to carry the slimes through the carbon bed without washing granular carbon over the top. For Pittsburgh Type SGL 8 X 30 mesh, the flow rates are 7 to 12 gpm/ft.^{2} depending on the solution temperature and the settled carbon bed depth is 8 to 10 ft., again depending upon temperature.

The carbon reactor itself is quite simple. Wood tanks or acid-resistant concrete vats can be used. It is necessary to have a good liquor distributor in the bottom of the bed to prevent short-circuiting of solution. Generally, the carbon will be supported on graded gravel. The net result is possibly a wooden tank, perforated filter tile, graded gravel, and activated carbon. So far we have seen no evidence of the need to regenerate or replace the carbon.

In studies to date, purchased or essentially pure sources of SO_2 and plant liquors have been used. No poisoning of the carbon has been observed. With pyrite being a logical source of SO_2, we wanted to check possible poisons from that source, such a arsenic, antimony, lead and zinc. Lead was not tested due to its low solubility in high sulfate systems. To a synthetic pregnant solution, the others were added in amounts of 0.1 g/l each. Stoichiometric SO_2 was added and a total of 314 column volumes were run through a carbon bed. The percent reduction remained constant throughout the run. This is a good indication that there should be no significant difference in carbon efficiency with roaster gas.

The following example is presented to show the potential significance of the SO_2 reduction system. The plant conditions are:

Copper production	60 tons/day
Flow to precipitation section	10,000 gpm
Acid addition to tails	4 lbs./lb. Cu precipitated
Delivered scrap cost	$55/Ton
Delivered acid cost	$15/Ton
SO_2 from pyrite	$15/Ton
Pregnant solution assay, g/l:	
Fe^{+++}	1.8
Fe^{++}	2.5
Cu^{++}	1.0
H_2SO_4	0.3

It is assumed the 0.3 g/l H_2SO_4 is consumed under present conditions and a total of 0.45 g/l would be consumed in the reduced solution.

The pertinent calculations regarding iron and acid for this plant with and without SO_2 reduction are given in the following table.

		Standard Practice	With SO_2 Reduction
Fe Factor	lb. Fe/lb. Cu	1.95	1.14
Fe^{++} in Tails	grams/liter	6.25	5.44
H_2SO_4 in Tails	grams/liter	0.0	3.0
Acid addition required	grams/liter	4.0	1.0
Fe Cost per day	Dollars ($)	6430	3770
SO_2 Cost per day	Dollars ($)	0	926
H_2SO_4 Cost per day	Dollars ($)	3600	900
Total Cost per day	Dollars ($)	10030	5596
Savings/1000 gpm/yr.	Dollars ($)		159624

You will note the savings in acid are as great as the savings in scrap. Whether full credit can be taken for the acid generated will depend on previous practice and attitude regarding acid addition.

SUMMARY

The profitability of leaching low grade or waste rock for copper is strongly dependent on acid and scrap iron requirements. As dumps age, the copper content of the pregnant liquor tends to lower and the iron level climbs. Due to bacterial and chemical oxidation, much of the dissolved iron reports in the pregnant liquor as ferric. This results in increased scrap consumption. At some point in time, the dumps are closed down when the solution grade does not justify the chemical and operating costs of recovery. Much of the scrap and acid costs can be offset by reducing the ferric with SO_2 which also generates sulfuric acid. Granular activated carbon is an expedient catalyst.

To take full advantage of the acid generated, control over retention time of solutions in contact with scrap iron is mandatory. Several types of precipitators are in use. The cone-type developed by Kennecott Copper Corporation would seem the most advantageous; however, one launder system employing SO_2 and activated carbon is in operation and the results to date are encouraging.

41. Electrodialysis

BOVET (1970) has claimed that electrodialysis is economically feasible for the treatment of process solutions and rinse waters from plating and metal finishing operations and for the treatment of acid mine drainage. ANDERSON, et al. (1971) reported energy requirements of 10 kWh per 1,000 U.S. gallons for electrodialysis and indicated that membrane fouling can be a serious problem.

More information about recent demonstration of electrodialysis reversal EDR for desalination of acid mine drainage at a Witwatersrand mine in 1984 can be requested from:

42. Reverse Osmosis

GOODLOE (1984), HERRIGAL (1984), and RESOURCES CONSERVATION CO. (1981) described the seeded slurry reverse osmosis process demonstrated at two sites, one for acid mine drainage water recovery at the ERPM mine, RAND MINES LTD., Brakpan, South Africa (a Witwatersrand gold mine) and one other non-mining application.

The combination of an innovative low-cost tubular R.O. system developed in South Africa with the seeded slurry concept where a slurry of gypsum crystals, which precipitate from the R.O. concentrate, is recycled back into the feedwater to prevent membrane fouling. This has made it possible to achieve excellent recoveries in the high 90% range from feed that is close to saturation with gypsum.

Although the purpose of the desalination plant was to demonstrate water recovery, the system also reduced levels of Cu, Pb, and Zn significantly as can be seen from the following results:

COPPER-LEAD-ZINC

	Feedwater	Recovered Product
Cu	0.3 mg/l	LT 0.01 mg/l
Pb	0.1 mg/l	LT 0.02 mg/l
Zn	2.0 mg/l	0.10 mg/l
pH	4	5

It appears that the seeded slurry reverse osmosis system very effectively removes copper, lead, and zinc to very low levels from acid mine drainage even at acidic pH values. It would be interesting to see how this process would perform on solutions with somewhat higher base metal levels.

This technology is said to cost around RO.50/m³ ($0.25/m³) to operate in South Africa (about U.S. $1.00/1000 gallons).

More information on this highly innovative breakthough technology is available from:

Precipitation

43. Soluble lead is usually removed from solution by precipitation and decantation including lime or caustic to precipitate lead hydroxide; soda ash to precipitate lead carbonate and phosphate to lead phosphate. Alum and ferrous and ferric sulfate coagulation have also been reported for lead treatment, as has ion exchange.

    In precipitation processes, lead is normally precipitated as the carbonate $PbCO_3$ or the hydroxide $Pb(OH)_2$.

44. Literature reports conflicting values of pH optima for lead precipitation as a hydroxide with the following being suggested:

Author	pH Recommended for Lead Precipitation
DEAN, et al. (1972)	pH 6.0
MILL, R.D. (1972)	pH 6.0-7.0
METAL FINISHING J. (1971)	pH 8.7-9.3
NETZER, et al. (1975	pH to 10.0
NILSSON (1971)	pH to 10.0
HEM and DURUM (1973)	pH 9.2-9.5 (Theoretical)
DAY, et al. (1974)	pH 9.2-9.5

NETZER, et al. (1975) found in bench scale tests that at the optimum pH 10.0, a residual lead value of 0.5 mg/l was achieved.

According to HEM and DURUM (1973), theoretical calculations indicate that the most efficient lead hydroxide precipitation occurs at 9.2-9.5.

45. HAAS and MILLER (1972) surveyed eight battery manufacturers' wastewater treatment and found that simple sedimentation was relatively ineffective in removing particulate lead. Data on four plants employing pH adjustment and sedimentation (for three of them) indicates that:

- Improved effluent quality was achieved at higher pH and longer settling times.
- Plant D, with no settling, had a very poor quality effluent.
- Plant D also uses ammonium hydroxide to raise the pH which results in a high soluble lead level. Ammonium is ineffective for lead precipitation because of lead amine complex formation.
- The best effluent was obtained by addition of caustic soda t pH 7.0 followed by 24-hour settling.

Treatment Practice and Effluent Lead Levels from Battery Plants

Plant	Treatment Chemical	pH	Settling Time (hr)	Effluent Lead (mg/l) Dissolved	Suspended	Total
A	Lime	6.8	30	0.30	0.18	0.48
B	Caustic	5.5	1	0.6	1.0	1.6
C	Caustic	7.0	24	0.02	0.02	0.04
D	Ammonia*	7.8	0	1.9	22	23.9

* Used for pH adjustment.

46. According to literature references, ammonia complexes lead and inhibits its precipitation from solution.

47. Solubility of lead carbonate is dependent on both treatment pH and carbonate concentration. For a fixed carbonate dosage, a broad range of pH (8.0-9.2) provides consistent treatment according to HEM and DURUM (1973) and DAY, et al. (1974). Precipitation by sodium carbonate addition plus sand filtration yielded an effluent with total lead at 0.2-3.8 mg/l and soluble lead of 0.1 mg/l at pH 6.4-8.7.

48. Pilot testwork by MARUYAMA, et al. (1972) demonstrated the importance of effective solid removal. An effluent with 5 mg Pb/l was precipitated by lime and $FeSO_4$ and then settled and filtered through a dual media filter. The results show lead values an order of magnitude lower after filtration compared with sedimentation alone.

Lead Removal by Precipitation and Sedimentation plus Filtration

Treatment Chemical	Treatment pH	Effluent Lead Concentration (mg/l)	
		Sedimentation	Filtration
Ferric Sulfate at 45 mg/l Fe	6.0	0.25	0.030
Lime at 260 mg/l + Ferric Sulfate at 20 mg/l Fe	10.0	0.25	0.029
Lime at 600 mg/l	11.5	0.20	0.019

49. Precipitation of dissolved lead by dolomite ($CaCO_3$, $MgCO_3$) as lead carbonate has been described by VOZNESENSKIC, et al. (1940). Lead wastewater was filtered through a calcined dolomite bed which precipitated dissolved lead. The dolomite filters were regenerated by backwashing with water to remove the lead carbonate formed in the process.

50. The reaction of lead with dolomite yielding insoluble lead carbonate results in very little lead reaching receiving streams from southeastern Missouri lead mines according to WIXSON, et al. (1969), JENNETT and WIXSON (1971), and BOLTER, et al. (1972). The lead mineralization occurs in a dolomitic hostrock, and the mill tailings contain ground dolomite. As the mill tailings are channeled through sedimentation basins and a meander system prior to release of the waste effluent, dolomite plus reacted lead carbonate are readily removed. Heavy metals precipitation is encouraged in the settling lagoons by the slightly basic nature of the waste at pH 7.5-8.2

JENNETT and WIXSON (1977) described the treatment of effluent from ST. JOE MINERALS' Fletcher Mine and Mill in which the minewater used to be treated in a series of five sedimentation ponds, and the effluent from the last pond is recycled to the milling operation resulting in a dramatically reduced heavy metal discharge to the receiving waters.

51. The Missouri new lead belt meander system also contains a thriving biological metals removal system. Plants, algae, and bacteria all contribute in the process to polish the effluent.

The Missouri Lead Study edited by WIXSON (1977) showed clear evidence of lead uptake to 4-5 mg/g (dry weight) of algae at the discharge point to the receiving stream which dropped to around 100 ppm within a mile or so from the tailings dam. Average water quality characteristics at the meander effluent stream were found by ERNST to be as follows as reported in WIXSON (1977):

	Cu	Pb	Zn
Dissolved Max.	0.015	0.025	0.08
TOTAL Max.	0.015	0.10	0.10
Dissolved Ave.	0.01	0.025	0.034
TOTAL Ave.	LT 0.01	0.038	0.034
Dissolved Min.	LT 0.01	LT 0.025	0.01
TOTAL Min.	LT 0.01	LT 0.025	0.01

This data shows the effectiveness of both the carbonate ore system and the biological polishing pond considering the large scale production of lead from the operation for which the above data describe the effluent.

52. At ST. JOE MINERALS' zinc smelter-refinery at Monaca, Pennsylvania, cadmium, lead, and zinc are precipitated by lime from the plant effluent and runoff waters to achieve the following results which are also reported in a trip report in Appendix I:

Influent	Ave.	1-Day Max.	30-Day Max.
Zn mg/l	14.5	77.2	21.3
Cd mg/l	2.5	16.7	3.9
Pb mg/l	2.6	16.0	4.0
Discharge After Lime, Settle, Filter			
Zn mg/l	0.55	3.34	0.75
Cd mg/l	0.19	1.02	0.22
Pb mg/l	0.17	0.45	0.12

The process employed to achieve these effluents includes settling followed by lime addition, settling in a clarifer, and multi-media filtration. Flocculant is used.

John M. Cigan of ST. JOE MINERALS pointed out that the low lead values are due to carbonate precipitation. There is adequate $CO_3^=$ in solution due to CO_2 uptake into the water from the air to precipitate lead; however, after a rainstorm, some Na_2CO_3 can be added if needed.

53. Lead Precipitation as Phosphate

CRANDELL and RODENBERG (1974) and ROHRER (1971) reported the use of sodium phosphate Na_3PO_4 to precipitate lead phosphate. The solubility of lead phosphate is determined by treatment pH and phosphate dosage. Treatment conditions are specified to exceed pH 7.0 with up to three times excess sodium phosphate added (3.7 pounds sodium phosphate per pound lead). This may result in excess phosphate levels. At pH 7.2-7.2, lead values were reduced to 0.2-0.6 mg/l total lead and 0.1 mg/l soluble lead.

54. Organic lead compounds generated, for example, in a tetraethyl lead plant did not respond to lime precipitation according to NOZAKI and HATOTANI (1967) but could be removed on strong acid cation exchange resins. Reductions of organic lead from 130-140 mg/l to 0.02-0.53 mg/l Pb were reported using ion exchange. The organic lead compounds were eluted from the resin by caustic soda.

55. Precipitation and removal of inorganic lead is facilitated by addition of ferrous sulfate according to ROBB (1961) and as noted above where ferrous sulfate is added in several lead treatment plants. Lime and ferrous sulfate were added to precipitate and coagulate lead leached from a nearby mine into a municipal water supply as described by J. INST. MUNICIP. ENG. (1957).

Alum coagulation at pH 6.8-7.0 has also been reported to coagulate lead from 17 to 1.3 mg/l according to NILSSON (1971).

56. Ion Exchange Removal of Lead

Successful ion exchange treatment has been claimed for both organic and inorganic lead. A study on treatment of an ammunition industry waste showed reduction of lead from 6.5 to 0.1 mg/l by precipitation. Ion exchange treatment of the effluent at pH 5.0-5.2 with a phosphoric acid resin reduced lead to 0.01 mg/l according to SHANNON (1973).

Elsewhere, an effluent level of 0.002 mg/l lead was achieved (LIEBIG, et al., 1943) although RANDOL INTERNATIONAL LTD. would question the ability to analyze to such a low detection limit in 1943.

Organic lead reductions from 140 mg/l to 0.02-0.50 mg/l Pb were claimed by NOZAKI and HATOTANI (1967) using a strong acid cation exchange resin.

57. A Summary of Reported Lead Treatment Processes and Efficiencies as extracted from PATTERSON (1975) is provided here:

Summary of Reported Lead Treatment Processes and Efficiencies.

Treatment	pH	Lead Concentration (mg/l) Initial	Lead Concentration (mg/l) Final	Percent Removal	Reference
Ion Exchange	5.0-5.2	0.1	0.01	90	15

58. HANWAY, et al. (1976) showed that metals in effluent samples could be reduced to 0.01 mg/l lead and 0.06 mg/l copper using starch xanthate to precipitate metals. Although the volume of the precipitated starch xanthate residue was small in comparison with that generated by conventional metal preciptation, the characteristics of the sludge were not particularly favorable. Sedimentation rates were slow, and the supernatant was often turbid and, on filtration, the residue clogged the filter media. The filter cake was sticky and had a moisture content of 60-80% water. The precipitate did not lend itself to metal stripping and re-xanthating. Adjustment of the pH to 8 with lime or caustic improved the results somewhat.

These authors discussed the advantages of using cellulose xanthate for metal removal because of its fibrous nature and the possibility of recyling the substrate. At a

xanthate dosage of 90 ppm, residual values of lead and zinc in an industrial wastewater could be reduced to 30 ug/l or less after 15-30 minute contact time. The residues settle rapidly to a pulp that filters readily leaving a clear supernatant and filtrate. A schematic of their proposed treatment scheme is shown below

Flowsheet of Cellulose Xanthate Process for Heavy Metal Removal.

Although the use of reusable cellulose xanthates appears to be intelligent and potentially practical, no users on a commercial scale have been identified, and there is no way to obtain comments on the pitfalls encountered with such a system.

WING, et al. (1974) described how the starch xanthate recovery properties could be dramatically improved using a cationic co-precipitant Poly (vinyl benzyl trimethyl ammonium chloride) PVBTMAC. It was shown that heavy metals could be dramatically removed from a synthetic solution, even at low pH. For example,

Metal	Concentration of Metal Ion mg/l	pH of Solution	Volume Starch Xanthate PVBTMAC Solution (1%) Added	Residual Metal Concentration ug/l
Cd^{++}	56.2	3.1	4.65 ml	8
Cr^{+++}	26.0	4.5	3.45 ml	52
Cu^{++}	31.8	3.0	4.50 ml	12
Pb^{++}	104.0	8	4.60	8
Hg^{++}	100.0	3.2	4.70	3.8
Ag^{++}	54.0	3.2	4.52	3
Zn^{++}	32.7	3.3	4.10	3,300

It is undersood that the work on starch xanthate with polymer addition has continued. Information has been requested from:

MR. ROBERT E. WING
Northern Regional Research Center
Agricultural Research Service
U.S. Dept. of Agriculture
1815 North University
Peoria, IL 61604
(309) 685-4011
Dr. Robert E. Wing

The PVBTMAC used in the development work was an experimental resin QX-2611.7 manufactured by the DOW CHEMICAL COMPANY, Midland, Michigan.

59. Another frontier treatment technology of potential interest, although to date inadequate information on cost has been made available to determine whether it could be considered for use in mine-mill effluent or process water treatment, is the DEVOE-HOLBEIN technology.

DEVOE-HOLBEIN (CANADA) LTD. has formulated experimental compositions which are capable of very specific metal removal and the removal of metals to extremely low levels. For example:

Metal	D-H Composition Used	Starting Concentration	Treated Water Concentration
Cd	B1	10 ppm	0.1 ppb
Cu	W-3	38.1 ppm	LT 1.0 ppt
Cu	A-1	381 ppm	3.8 ppt

Metal Cation	g Metal Removed per Liter DX-2000
Ag^{+1}	300
Au^{+1}	550
Cd^{+2}	155
Cu^{+2}	89
Pb	Not Shown
Zn^{+2}	91

The chelation compound DX-2000 is not designed for solution polishing to below 0.30-2.0 ppm levels. It is designed for macro removal of metals that are complexed and, therefore, do not precipitate easily using other processes.

The same company also manufactures an insoluble starch xanthate product designed for solution polishing for which a technical data sheet is shown below.

POLLUTION TECHNOLOGY SYSTEMS, INC. also offers design and engineering services along with their process. More information is available from:

Mike Coward
Manager, Systems Engineering

61. RANDALL, et al. (1975) of the U.S. Dept. of Agriculture were granted U.S. Patent 3,925,192 for the removal of metal ions from water using formaldehyde-modified nut waste, e.g., peanut shells. Removal of mercury, silver, nickel, and lead to sub-ppm levels was demonstrated, but it is not clear what volume of water can be treated by a ton of modified nut waste. Possibly, the nut waste and formaldehyde provide organic energy for anaerobic bacteria that convert sulfates to sulfide and may be the mechanism?

    45 g formaldehyde modified hemlock bark was able to remove lead to less than 0.3 ppm from 60 l of solution containing 20 mg/l Pb.

62. Industrial effluent treatment for zinc removal has been achieved using precipitation and ion exchange. The most common precipitation method is by lime precipitation or precipitation with caustic. Generally, treatment is not for zinc alone.

63. Cyanide or chromate are often present with zinc in plating wastes and cyanide with zinc in many gold or leaching operations. Cyanide and chromate must be removed before zinc can be precipitated as a hydroxide.

INDUSTRIAL WASTEWATER MANAGEMENT PRODUCTS AND SERVICES

TECHNICAL DATA SHEET

NOMENCLATURE:

DX-2000

GRADE:

Technical

TYPICAL PROPERTIES:

Physical Form	Yellow Liquid
Specific Gravity	1.140 @ 30 C
pH	10.5
Solubility	Soluble in Water
Concentration	40 percent

CONTAINERS:

500 Net Pounds/55 Gallons
Phenolic Lined

USES:

DX-2000 is a buffered organic material that effectively precipitates complexed or chelated cationic heavy metal concentrations of 10 mg/l or greater from difficult-to-treat industrial process waters. The product is effective over a pH range of 3 to 11. Residual heavy metal concentrations following treatment with DX-2000 are usually well below local, state and EPA-NPDES discharge limit permit requirements.

APPLICATION:

Batch or continous flow injection of predetermined dosage for maximum heavy metal cation removal from process aqueous solution containing constituents greater than 10ppm. Thoroughly mix, allowing adequate contact time. Cationic polymer may aid in sludge settling and removal. Sludge is removed by filtration, clarification or centrifuge. Effective cation heavy metal removal over a pH range of 3-11. Adjustments in dosage and pH may optimize effectivness and economics.

RECOMMENDED DOSAGE:

Metal Cation	Grams of Metal Removed per liter DX-2000 (1)
Ag^{+1}	300
Au^{+1}	550
Cd^{+2}	155
Co^{+2}	83
Cu^{+2}	89
Fe^{+2}	78
Hg^{+2}	280
Mn^{+2}	77
Ni^{+2}	82
Zn^{+2}	91

NOTE: (1) Based on Molecular Weight Theoretical Capacity.

INDUSTRIAL WASTEWATER MANAGEMENT PRODUCTS AND SERVICES

NOMENCLATURE:

Insoluble Starch Xanthate
ISX/5-CM

GRADE:

Technical

DESCRIPTION:

ISX/5-CM is a yellow colored highly crosslinked xanthate starch in powder form with a light pungent odor.

PARTICLE SIZE:

20 Microns, aqueous solution

COMPOSITION:

Sulfur Total	18 Percent
Sulfur Xanthate	12 Percent
Ash (Sodium & Magnesium)	18 Percent
Caustic	14 Percent
H_2O	35 Percent

TYPICAL PROPERTIES:

Stored	45 F	6 Months
Stored	70 F	3 Percent(1)

NOTE: (1) Xanthate sulfur reduction in 7 days.

CONTAINERS:

Standard unit 25 & 250 pounds net.

USES:

Instantaneous heavy metal cation removal upon contact from industrial and mining process and wastewaters. As an inexpensive final polish of singular or combined heavy metal cations of less than 10ppm in aqueous solution.

APPLICATION:

Filter precoat, batch or slurry. Easily dewaters to less than 50 percent by volume. Recommended pH 3-11 with maximum effectiveness at a pH of approximately 7 for most heavy metal cations. Recommended weight capacity ratios of ISX/5-CM for heavy metal cations in aqueous solution are as follows:

Ag^{+1}	Silver	6.5:1
Au^{+1}	Gold	3.5:1
Cd^{+2}	Cadmium	12.0:1
Co^{+2}	Cobalt	23.0:1
Cr^{+3}	Chromium	40.0:1
Cu^{+2}	Copper	21.0:1
Fe^{+2}	Iron	24.0:1
Hg^{+2}	Mercury	7.0:1
Mn^{+2}	Manganese	25.0:1
Ni^{+2}	Nickel	23.0:1
Pb^{+2}	Lead	6.5:1
Sn^{+2}	Tin	12.0:1
Zn^{+2}	Zinc	21.0:1

Dependent on end user specific needs, variations of pH and ISX/5-CM weight capacity ratios will optimize product efficiency.

PTS 1153

64. Settling efficiency of zinc hydroxide precipitate affects effluent concentrations with significant improvement if the effluent is filtered after decantation.

65. Sulfide precipitation at pH 2 has been reported to achieve "complete removal" of zinc from an electrolytic nickel recovery system by BANERJEE and BANERJEE (1952).

Sodium sulfide treatment of a gold ore refining waste initially containing zinc at 42 mg/l achieved precipitation to 1.16 mg/l at a treatment pH of 7 according to ROSEHART and LEE (1972). Treatment of the same waste by caustic at pH 10 reduced zinc to 0.02 mg/l.

66. LARSEN, et al. (1973) reported that treatment of acid mine drainage containing 122-294 mg Zn/l by lime addition to pH 5.0-5.5 for Al and Fe precipitation followed by sulfide addition at pH 5.5-6.4 produced variable zinc levels in the effluent ranging from 0.20-30.0 mg/l, indicating that sulfide precipitation of zinc may not always be straightforward.

67. DUPONT's Kastone process employing copper catalyst, hydrogen peroxide, and stabilizers oxidizes cyanide and promotes the formation of metal oxides rather than hydroxides which, in small metal finishing plants, are more easily filtered.

On the other hand, CHAMBERLAIN and ANDERSON (1971) were able to demonstrate selective zinc removal from 6 to 0.4 mg/l from cooling tower blowdown.

PATTERSON (1975) concluded that lime precipitation of zinc can generally achieve levels below 1 mg/l, although assurance of consistant removal of the precipitate from the effluent may require sand filtration and adequate pH control.

68. Ion exchange can be used as a recovery method for zinc at very high concentrations although no cases are known where this is economically used on a commercial scale except at viscous rayon plants where zinc is present at very high levels. For mining and metallurgical operations, IX would be most unlikely to be useful except possibly for polishing of a final effluent. Laboratory studies by KANTAWALA and TOMLINSON (1964) found that at flow rates of 2.5 gal/hr/ft^2, ion exchange was less effective than lime precipitation for zinc removal.

WILMOTH, et al. (1979) reported that reverse osmosis and ion exchange were slightly more effective than neutralization for removal of As, Cd, Cu, Hg, Ni, Se, and Zn.

69. The demonstration seeded slurry reverse osmosis system installed at ERPM (RAND MINES, South Africa), although installed to demonstrate water recovery, did reduce zinc from 2 ppm in the feedwater to 0.1 ppm Zn in the product demonstrating that

zinc can be effectively removed by reverse osmosis at pH 4-5 through a cellulose acetate membrane. More information on seeded slurry R.O. can be obtained from

70. As mentioned above in the discussion on copper and lead removal, very low levels of zinc can be achieved in effluents treated by starch or cellulose xanthates and also with the compositions of DEVOE-HOLBEIN (CANADA), INC., which in tests have achieved removal of zinc to below 20 parts per trillion.

71. HERMAN (?) described the use of the high density sludge HDS process to drop soluble copper, cadmium, zinc, nickel, and lead to below 0.1 ppm at a single pH level while generating a sludge with in excess of 20% solids compared with 1% solids by conventional neutralization.

72. ST. JOE MINERALS reported removing zinc by lime precipitation from 27 ppm Zn and 1.65 ppm Pb in the feed stream to 2.6 ppm Zn and 1.5 ppm Pb in the reactor clarifier overfow and to 0.11 ppm Zn and 0.17 ppm Pb in the SVG overflow at pH 9.

73. COCHECI, et al. (1983) reported purification of effluents from a nonferrous metallurgical operation by precipitation with calcium polysulfide and simultaneous recovery of useful metals.

74. <u>Ion Flotation</u>

ISUMI, et al. (1976) described removal of heavy metal ions, i.e., Cu, Pb, Zn, Ni, Cd, Co, and Mn, which were recovered from real and simulated waste waters by a foam separation method using N-decanoyl diethylenetriamine [N-[2-[(2-aminoethyl) amino]ethyl]decanamide]. The reagent forms soluble and foamy complexes with the metals.

In this process, Cu and Zn are recovered from the precipitate. The supernatant is filtered, neutralized, and treated again with Ca polysulfide and refiltered to give an effluent that meets disposal standards.

75. IKEBE (1974) described an interesting chemical scheme for removal of heavy metal ions from metallurgical and mining effluents.

Heavy metal ions, especially Cu^{2+} and Hg^{2+}, are sequestered with a dealkyldithiocarbamic acid and are treated with NaOH and Na_2S or two equivalents of the metal dialkyldithiocarbamate in a suspension of the salt with a pulp concentration of 1-3

mole/l to produce a scum of CuS or PbS. The sulfide scum is separated either by precipitation or flotation and after regeneration, the dialkyldithiocarbamate ion is recycled. The process is useful in treating waste water containing heavy metal ions, and the dialkyldithiocarbamate can be recovered quantitatively and recycled.

The use of NaOH in this process improves the separation efficiency by preventing the formation of colloidal CuS. Thus, $Cu[S(S)CNEt_2]_2$ was suspended in one l water (pulp density 5×10^{-2} mole/l), and 2 g NaOH were added and stirred. Na_2S at one mole/l was then added, and the CuS formed was removed by precipitation. When one equivalent of Na_2S was added, approximately 100% of the $NaS(S)CNEt_2$ was recovered. The light yellow liquid recovered had a pH of 12.8 and contained only 1-2 ppm Cu. The recovered liquid could be recycled for additional Cu removal. When NaOH was not used in a similar process, 100% of the $NaS(S)CNEt_2$ was recovered, but about 35% of the colloidal CuS was also present in the recovered liquid.

The author, according to Chemical Abstracts CA 83(8):65183V, is employed at the SUMITOMO CHEMICAL COMPANY in Japan.

76. KAIDA, et al. (1978) described a bench scale treatment of mine effluent containing iron, copper, Cd, and zinc. The process employs catalytic air oxidation of ferrous to ferric ions using $NaNO_2$, fractional precipitation of $Fe(OH)_3$, neutralization, coagulation and sedimentation, flotation, and sludge treatment. The concentration of heavy metals in the effluent was reduced from 549 mg/l to 0.91 mg/l for Zn; 4.92 to 0.04 mg/l for Cd, Cu and Fe were not detected in the treated effluent. The unusual aspect of this process is the oxidation of Fe^{2+} to Fe^{3+} at low pH and the removal of Cu and Fe to their detection limit if the claim is accurate.

NOTE

This report is based on information provided by literally hundreds of individuals in mining, engineering, and consulting companies. The author gratefully acknowledges this industry support without which RANDOL surveys would not be possible.

The information contained herein is submitted on a "best efforts" basis. Although an attempt has been made to avoid misleading errors, this report should be used by sponsors at their own risk and subject to verification. Since it deals with a pioneering field, it has not been altogether possible to avoid speculative assessments.

Some of the information may possibly be "sensitive." This report is submitted to you on condition that sponsors hold its contents strictly confidential.

CONVERSION FACTORS

Grains per gallon (U.S.)	Milligrams per liter	17.12
Milligrams per liter	Grains per gallon (U.S.)	0.05841
Milligrams per liter	Tons per acre-foot	.001360
Tons per acre	Metric tons per hectare	2.217
Grams	Ounces (avoirdupois)	.03527
Ounces (avoirdupois)	Grams	28.35
Gallons (Imperial)	Gallons (U.S.)	1.2009
Acre-feet	Gallons	325,851
Acre-feet	Cubic feet	43,560
Cubic feet	Cubic meters	.028317
Cubic feet	Gallons	7.481
Cubic meters	U.S. Gallons	264.2
Cubic meters	Imp. Gallons	220.0
1,000 m^3/d	I gpm	152.8
1,000 m^3/d	U.S. gpm	183.6
U.S. gallon	Cubic meter	0.3785

CHAPTER 40 - CYANIDE 2294

Summary 2294
Cyanides in Metallurgical Effluents 2296
Influence of Metallurgical Process on Cyanide Levels 2297
Table 0: Cyanide Consumption Estimates 2300
Table 1: Homestake Mine, Wastewater Characteristics 2301
Table 2: Ontario Gold Mining Effluents 2302
Table 3: Chemical Analyses of Barren Solutions and Tailings Pond Effluents 2303
Table 4: Gold Mill Tailings 2304
The Effects of Cynide-Bearing Gold Tailing Disposal on Water Quality in the Witwatersrand, South Africa, ADRIAN SMITH, et al. (1984) 2309
The Concentration of the Complex Cyanides in Flotation Tailings 2319
Table 5: Est. Max. Concentration of Cyanide in Flotation Tailings - AMAX ESI 2321
Advantages of Cyanide 2326
Contraversial Aspects of Cyanide 2327
Regulations Concerning Cyanide in Tailings and Effluents 2328
Cyanide Regulations 2329
Examples of Some U.S. Effluent Regulations 2332
Cyanide Limits in Effluent: Brazil 2334
Canadian Cyanide Effluent Regulations 2335
Examples of Limits for Cyanide - Canada 2337
Process Requirement, Toxicity of Cyanide 2338
Toxicity Effects of Cyanide 2339
Chemistry of Cyanide 2339
Cyanide Destruction 2340
Table 6: Solubilities of Ferrocyanides and Ferricyanides 2342
The Nature of Toxicity of Complexed Cyanides in Flotation Tailings 2344
Rationale for the Establishment of Ontario's Provincial Water Quality Objectives 2347
Chemistry of Cyanide and Cyanide Removal 2353
Table 7: Stability of Metal-Cyanide Complexes 2353
Table 8: Stability of Metal Cyanide Complexes 2354

Table 9: Est. Capabilities of Processes for Cyanide Removal from Gold Mill Effluents - Summary 2355
Analytical Determination of Cyanides 2361
Total Cyanide Analysis 2363
APHA-AWWA and ASTM Method 2363
Weak Acid Dissociable Cyanide 2366
ASTM Method C 2366
INCO Method for Cyanide Analysis 2367
The Determination of Cyanide in Waters 2369
The Determination of Cyanides in the Hydrometalligurical Processing of Gold, C. POHLANDT (1984) 2371
Determination of Cyanides in Drinking and Natural Waters and Industrial Effluents 2377
CYANIDE Colorimetric-Chloramine-T, Pyridine-Pyrozolone 2389
Cyanide Analysis by Specific Ion Electrode 2399
Cyanide Destruction in Gold and Silver Operations 2409
Cyanide Destruction Plants in Canada 2409
Cyanide Destruction in the U.S.A. 2412
Table 10: Results from Homestake Pilot Plant 2414
Cyanide Destruction - Rest of the World 2414
Table 11: Profile of Gold Mills 2416
Overview of Cyanide Treatment Methods for Gold Mill Effluents, JAMES S. SCOTT (1984) 2419
Overview of Cyanide Treatment Costs 2441
Alkaline Chlorination 2444
Performance Capability 2444
Table 12: Reactions Involved in the Chlorination of Cyanide 2445
Chemistry of Alkaline Chlorination 2447
Description of Alkaline Chlorination Process 2447
Alkaline Chlorination Process Control 2448
Reagent Usage 2450
Advantages and Disadvantages of Alkaline Chlorination 2450
Applicability of Alkaline Chlorination 2451
Scottie Gold, B.C. 2452
DuPont Baker Mine, B.C. 2452
Carolin Mines, Ladner Creek Mill, B.C. 2453
Giant Yellowknife Mines, N.W.T. 2453
Westmin Resources, B.C. 2455
Supplement to "Pollution Control at Western Mines' Myra Falls Operation" 2457
Pollution Control at Myra Falls 2464
Noranda Grey Eagle Mines, Inc. 2467

Noranda Research Centre Memorandum 2469

CHAPTER 42 - IRON Fe 2737

Introduction 2737
Occurrence of Iron 2738
Environmental Impact of Iron 2739
Regulatory Limits for Iron 2739
Treatment for Iron 2739
Summary of North American Water Quality Criteria for Iron 2740
Summary of Municipal Plant Performance for Iron 2743
Treatment of Iron in Acid Mine Drainage 2744
Treatment Costs 2745
Discussion 2745
Biological Oxidation of Ferrous Iron 2746
Dissolved Air Flotation 2747
Reverse Osmosis 2747
Summary of Results by WILMOTH and SCOTT (1976) 2748
Catalytic Oxidation of Iron 2748
References 2749

CHAPTER 43 - MANGANESE Mn 2751

Occurrence of Manganese in the Mine-Mill Environment 2751
Summary of PEDCO (1983) Survey: Manganese 2753
Summary of North American Water Quality Criteria for Manganese 2755
Environmental Sensitivity of Manganese 2756
Regulatory Limits for Manganese 2756
Manganese Solubility eH-pH 2757
Treatment for Manganese 2758
Permanganate Requirement for Manganous Manganese 2760
Manganese (Total) in Mine-Mill Effluents 2763
Examples:
Mount Emmons, Colorado 2764
Gilman, Colorado 2765
Enoxy Coal, Inc. 2766
The HDS Process 2766
Rössing Uranium Ltd. 2766
Orkney Municipality, South Africa 2767
Vaal Reefs Exploration and Mining Company 2768
Rand Mines Ltd., ERPM Seeded Slurry R.O. 2768
Bureau of Mines, Pittsburgh, PA 2769
ARGO Tunnel Test, Wannamaker Continuous Concentrator 2769
Dry MgO Precipitation of Metals 2770
Sulfide Precipitation 2770
Two-Stage Process Chemically Treats Mine Drainage:
LARSON and ROSS (1976) 2771
References 2772

CHAPTER 44 - MERCURY Hg 2776

- Introduction 2776
- Occurrence of Mercury in the Mine-Mill Environment 2776
  - PEDCO (1983) Data Summary - Mercury 2778
- Regulatory Limits for Mercury in Effluents 2780
  North American Water Quality Criteria for Mercury 2781
- Mercury Limits in Mine-Mill Operating Permits 2783
- Effects of Mercury on Metallurgical Efficiency 2783
- Environmental Sensitivity - Mercury 2784
- Treatment for Mercury Removal 2786
  - Selective Leaching: Gold and Silver Cyanidation 2786
  - Mercury Removal from Gold Mill Solutions/Effluents 2787
  - Precipitation 2788

Sulfex Process 2789
Boliden Metall, Sweden 2789
- Ion Exchange 2791
Methyl Mercury and Inorganic Mercury Collection by a Selective Chelating Resin by STEPHEN S. LAW (1971) 2793
Adsorption of Mercury from Aqueous Solutions by Polyethelenimine-Modified Wool Fibers by FREELAND, et al. (1974) 2795
Removal of Mercury from Aqueous Solutions by N-(2-Aminsethyl) Aminodeoxycellulose Cotten by SNYDER and VIGO (1974) 2796
- Chelating Compounds 2797
- Devoe-Holbein Compositions 2798
- Coagulation Treatment 2799
- Activated Carbon 2799
- Reduction Processes 2800
- Adsorption Processes 2801
- Other Technology 2802
- Conclusions 2802
° Analysis of Mercury Using a Gold Film Detector by McNERNEY (1983) 2803
° Determination of Nanogram Quantities of Mercury in Liquid Matrices by a Gold Film Mercury Detector by P. J. MURPHY (1979) 2807
° Quantitative Analysis of Mercury Vapor by Gold Film Sensors, RICHARD T. McNERNEY (1983) 2809
° References 2812

CHAPTER 45 - MOLYBDENUM Mo 2817

Introduction 2817
Occurrence of Molybdenum in the Mine-Mill Environment 2818
Summary of PEDCO (1983) Data 2819
Environmental Sensitivity - Molybdenum 2820
Regulatory Limits for Molybdenum 2821
Treatment for Molybdenum Removal 2822
Biological Removal of Molybdenum 2822
Activated Charcoal Adsorption of Molybdenum 2822
Development of Waste Water Treatment at the Climax Mine, RICHARD D. GOTT and JOHN M. LABERTY (1977) 2823
Treating Tailings Waters from Moly Operations - A Review, GOPALAN RAMADORAI (1978) 2831
Process for Recovering Molybdenum and Tungsten from Mining Wastewater, RAMIREZ, et al. (1980), U.S. Patent 4,219,416 2835

Ion Exchange 2839
Coagulation with Iron 2839
Geochemical Adsorption 2840
Removal of Selected Inorganic Pollutants from Uranium Mine Waste Water by Biological Method, BRIERLEY, et al. Excerpt 2842
References 2843

CHAPTER 46 - ORGANICS 2844

Introduction 2844
Possible Sources of Organic Species in Mine-Mill Solutions 2845
Environmental Sensitivity to Hydrocarbons and Phenols 2846
Regulatory Limits on Oil, Grease, and Organics 2847
Effects of Organics on Mine-Mill Performance 2848
Molybdenite Recovery vs. pH for Demin. vs. Sewage Effluent 2852
Prevention of Organics Contamination of Process Water/Effluents 2854
Treatment for Removal of Organics 2856
Physical Skimmers 2856
Adsorption Devices 2857
Organics Containment Booms 2858
Oil Recovery Systems 2858
Organic Solvent Removal and Recovery 2858
Carbon Adsorption systems 2859
Biological Processes 2859
Treatment for Removal of Organics 2860
Charcoal Addition 2860
Ageing 2860
Biological Meander System 2861
Replace Organic With Aqueous Hydraulic Power 2861
Activated Carbon-Simmergo 2862
DAF 2863
Humic Acid Removal on Resins 2863
Supercharged Oxygenated Activated Sludge VITOX 2865
Measurement of Organics in Water 2866
References 2868

CHAPTER 47 - PHOSPHATE REMOVAL PO_4^{3-} 2871

Introduction 2871
Occurrence of Phosphates in Water 2871

Phosphates in Mine-Mill Environments 2872
Influence of Phosphate on Metallurgical Processes 2873
Variation of PO_4^{-3} in Treated Sewage Water 2874
Environmental Sensitivity to Phosphorus 2875
Regulatory Limits for Phosphorus 2877
Removal of Phosphorus 2877
Chemical Coagulation 2878
Performance - Coagulation 2878
Flexibility 2879
Biological Phosphate Removal 2881
Biological Phosphate Removal - Plants 2882
Technical Guide on Biological Nutrient Removal by MJNP SIMPKINS and A. GERBER 2883

Summary

Cyanide is metallurgically the most suitable lixiviant for the leaching of gold and silver from many ores and concentrates and gold from calcines after the roasting of otherwise refractory sulfide concentrates. Cyanide is also used as a depressant in the selective flotation of sulfide minerals, for example in the depression of pyrite from base mineral sulfides, and in the separation of copper-lead and copper-molybdenum sulfide flotation bulk concentrates.

Cyanide also usually occurs as a metallurgical contaminant in groundwater around aluminum cell potlines as a result of interaction between air and the carbon electrodes. 200 ppm cyanide as ferrocyanide was detected in groundwater around a typical potline. Cyanide is generated in the manufacture of coke and processes have been or are being developed for its removal from effluent streams in which it occurs.

At a current cost of US$0.40 - $0.80/lb depending on location, cyanide is used in relatively small dosages (Average 1-1.5 lbs/ton ore) and offers a significant economic advantage over other leaching reagents for the conventional leaching of gold and silver. Without the development of cyanide as a leaching means, it is possible that the full potential of the Witwatersrand - a major source of the world's accumulated gold supply - might never have been reachable.

Cyanide also offers the definite environmental advantage of being "biodegradable" under favorable climatic conditions and there is evidence that cyanide does not persist for a

long time in the environment (HUIATT, 1984). Yet the lethal toxicity of cyanide in large doses to mammals and its use in executions or dramatic suicide attempts has set cyanide apart from other equally or more toxic reagents and invokes a degree of unjustifiable paranoia in the minds of those not familiar with its use.

Although low levels of cyanide generally encountered in metallurgical operations and treated with appropriate respect are not difficult to handle safely without accident or injury to humans, levels as low as 0.1 ppm and below of free cyande are shown to be very detrimental to aquatic life. Much more insight and knowledge is needed as to the environmental effects and "non-effects" of cyanide in the forms in which it occurs in effluent streams to determine what levels and forms can safely be tolerated in nature. Meanwhile, regulations controlling the discharge of cyanide and complex cyanides in effluents are in several countries not yet clearly formulated.

This section of the report deals with how cyanide can be decomposed or removed from metallurgical effluents and tailings. Control of and understanding the environmental and process effects of cyanide requires accurate analyses, and it is essential therefore to review the various analytical methods that are available, the sources of interference and what the results obtained by each method mean. There is likely to be continued controversy and debate as to the merits of existing regulatory limits or what additional limits need to be set and on which method of analysis the limits should be based. For this reason cyanide analysis is discussed here in some depth.

There are several cyanide removal processes available and it is important to gain an insight into what species are removed, what byproducts are generated and how well the processes work in practice compared with laboratory tests. Climate, regional regulatory requirements and the nature of effluent chemistry as well as the receiving waters all have an effect on the applicability of the various cyanide decomposition and removal processes. Finally it is necessary to gather and review data on the cost and performance of several of these processes installed in actual plant conditions.

Some argue that environmental toxicity data presented so far are meaningless due to the uncertainties in analysis methods, and because cyanide used in the toxicity test is dosed to synthetic solutions that do not represent real mine effluents. Others have recently produced a large amount of data on toxicity of cyanide and complex cyanide which they have presented as compelling evidence. The data available on the whole subject is presented here with the intention of remaining impartial and without making any recommendations as to how it should be regulated.

Complete books have and will be written on the subject, meanwhile the most pertinent points considered to be of practical value on cyanide treatment processes are discussed under the following headings:

- Cyanide in metallurgical effluents
- The advantages of cyanide
- Regulations governing cyanide in tailings and effluents
- Motivation to remove cyanide from effluents
- The chemistry of cyanide
- Analytical determination of "cyanides"
- Methods for removing or destroying "cyanides"

Cyanides in Metallurgical Effluents

The greatest use of cyanide in mineral processing is for gold leaching. Free world consumption of cyanide for this purpose amounts to a guestimated 75,000 tons per year of sodium and calcium cyanides combined.

Canada for example, in 1979, produced around 60 tons of gold by treating 6.2 million tons of ore per year consuming 2,820 tons of sodium and calcium cyanide annually. This works out to 17,000 tons ore per day requiring 7,700 Kg sodium and cyanide daily according to SCOTT & INGLES (1981).

By far the largest amount of cyanide used for gold processing is consumed in South Africa where a guestimated 130,000 tons per year of calcium and sodium cyanide was consumed in this industry in 1983, nearly all of it in the giant Witwatersrand and Orange Free State gold mines. In this generally arid country water is recycled on a macro scale yet cyanide contamination problems even there where the gold mining industry forms the nucleus of the industrial heartland of the country, could be rated as minimal, if any.

Cyanide in gold and silver leaching effluents occur in several streams. Firstly, some cyanide remains in the leached tailings from the gold plant and is pumped to the tailings impoundment with the tailings or, if backfill is practiced, some may return underground with the sand fraction of mill tailings. Table 1 shows the wastewater

characteristics of minewater and tailings impoundment water from the Homestake Mine as reported by WHITLOCK, Terry I., and MUDDER, James L. (1984).

Data on gold mining effluents from seven gold mines in Ontario as reported by MILGRAM (1982) are shown in Table 2.

Table 3 reports data on cyanide and thiocyanate as they appeared in the proceedings of a comprehensive Workshop Proceedings edited by HUIATT, et al. (1982).

Table 4 lists water quality data for several additional Canadian mills as well as one South African gold plant effluent.

Influence of Metallurgical Process on Cyanide Levels

Several process selection decisions have a significant effect on the cyanide levels in gold and silver recovery tailings and effluents. The most significant of these is the extent to which cyanide bearing solutions are recirculated.

1) Conventional Leach - Merrill-Crowe Zn Precipitation

Non-cyanide grinding circuit
Cyanide leach circuit
Filtration or CCD washing recovers 99% Au and CN^-
Repulp of tailings with tailings return water

2) Carbon in pulp

Crush
Grind with or without cyanide
Leach with or without carbon
Tailings to tailings pond without washing

3) <u>Heap leaching</u>

In the first and third basic process flowsheets it will be noted that the opportunity exists to recycle cyanide with the recirculating leach solution.

In the case of the conventional leach/Merrill-Crowe process it is possible to maintain the grinding circuit as cyanide free. After leaching and solid/liquid separation gold and soluble cyanides are washed from the pulp and after gold is recovered the barren solution is returned to the front end of the leach. As undesirable soluble salts build up to a point that they interfere with the process the system is bled and solution made up with fresh water. The extent of the barren bleed depends on the nature of the ore.

In the carbon in pulp process which is more applicable to gold ores than silver, the cyanide present in the leach pulp advances through the CIP step to tailings. There is some recycle of cyanide possible in tailings return water but mostly it is lost through natural or biodegradation.

When the gold or silver ore contains cyanide-soluble copper then an excess of cyanide over that required to complex the copper must usually be added to leach gold and silver. Since copper cyanide reports as "free" cyanide, usually 5 moles cyanide are added per mole copper to find the correct amount needed. For example, the Battle Mountain operations of Duval Corp. treating a copper rich ore use 2 Kg NaCN/ton ore compared with the industry average of 0.7 Kg/t (1.5 lbs NaCN/t). Noranda Grey Eagle Mines with a higher copper level uses about 4 Kg NaCN/t ore.

As copper cyanides build up in the solution due to recycling of solution then it reaches a point at which it interferes with zinc precipitation of gold and silver. Then the "poisoned" cyanide solution historically called foul liquor is partially purged from the system as a barren bleed and made up with fresh solution.

In general CIP is more applicable for high copper and nickel ores than the Merrill-Crowe conventional process. However, to make the carbon adsorption process work best it is then necessary to maintain an excess of cyanide in solution - which ends up in the tailings. Also, because of the high copper values the tailings solution cannot be recycled to the leaching step without expensive special steps which are not currently known to be cost effective.

Consequently tailings from CIP circuits are likely to be higher in cyanide than tailings from the conventional agitation leach and zinc precipitation processes even for the treatment of normal free milling ores low in copper and nickel.

TABLE O
Cyanide Consumption Estimates

	Year	Reference	Tons/day Ore	Kg cyanide/d	Kg cyanide ton ore	tons cyanide/ year

THE EFFECTS OF CYANIDE-BEARING, GOLD TAILINGS DISPOSAL ON WATER QUALITY IN THE WITWATERSRAND, SOUTH AFRICA

by
Adrian Smith , Alison Dehrmann and Rob Pullen

INTRODUCTION

The workshop on "Cyanide in Mineral Processing" held in Salt Lake City in February 1982 identified the following problems with respect to the fate of cyanide in the environment:

> "Limited information is available on the fate of cyanide from leaching and flotation operations in soils, aquifers, and/or old tailings dumps. Temperature, natural oxidants, sunlight, bacteria, organic and inorganic materials, type of soils, water chemistry, mineral constituents of tailings, permeabilities of soils and tailings, type of cyanide compound, concentration of the cyanide compound, rate of migration of cyanides, and materials of construction and design of leach pads and tailings ponds all have an effect on the ultimate fate of cyanide in the environment. Accurate knowledge of the fate of cyanide is necessary if meaningful, practical regulations are to be established for monitoring or controlling mineral process effluents. Nearly all regulations are now handled on a site-specific basis. Any information concerning fate of cyanides and related compounds will be of considerable value to the mine operator and to the monitoring agency."

For the past two years, Steffen Robertson and Kirsten have been cumulating information on the levels of cyanides in tailings, surface waters and near-surface groundwaters associated with cyanide-bearing gold tailings disposal from Witwatersrand, South Africa. In addition, cyanide data has been collated from the drilling and monitoring of tailings impoundments allowing the construction of a cyanide profile through the tailings mass. It is believed that these data will serve as a useful adjunct to data from North America tailings disposal operations.

The collection of data is not complete. This paper represents a presentation of the data available as of November 1984 and may be considered an interim statement of results. Due to the confidential nature of individual data, no specific sources have been identified and remain entirely anonymous. This does not detach from the value of the data which are considered to represent the Witwatersrand area as a whole.

Steffen, Robertson & Kirsten (B.C.) Inc., Vancouver, Canada.
Steffen, Robertson & Kirsten (Mining) Inc., Johannesburg, South Africa.

BACKGROUND

It is almost one hundred years since the first gold was mined in 1886 on the Witwatersrand, the "ridge of white waters", in the Transvaal Highveld of South Africa. Mining on the Witwatersrand, the principal centre of the South African gold mining industry, has resulted in the accumulation of over 300 tailings impoundments through the area. The majority of the mills producing these tailings used sodium cyanide in the gold extraction process and hence there is normally a residual quantity of unused cyanide reporting to the process tailings.

The combination of geology and climatic regime on the Highveld are such to have produced a groundwater regime over a significant part of the area where two principal aquifers are formed:

- a deep, regional aquifer (in the Transvaal dolomites) bearing good quality groundwater; and
- a near-surface, sometimes non-perennial aquifer, which is normally in hydraulic continuity with the surface waters of the area, when they are present.

The latter aquifer, developed due to the intense weathering of the surficial rocks of the Witwatersrand, is highly permeable and relatively vunerable to surface pollution sources. Slow leakage may or may not occur from this near-surface aquifer to the deeper, regional groundwater. The disposal of cyanide bearing, gold tailings can represent a potential pollution threat to both aquifer regimes by direct runoff, erosion of tailings and seepage from the tailings impoundments themselves.

REGULATORY CONTROL

Discharge of cyanide-bearing effluents or seepage from mining and milling operations is covered by regulations made under the Water Amendments Act 1984 (No. 9330), or, if discharge is made to a potable water resource, in terms of the South African Bureau of Standards (SABS 241-1971) specifications.

Discharge is regulated in terms of total cyanide levels. The general effluent standards specify a total cyanide level of 0.5 mg/L, while the potable water standards are 0.01 mg/L "recommended" limit and 0.2 mg/L "maximum allowable" level. These are broadly similar to both World Health Organization and U.S. Public Health recommendations.

MONITORING PROGRAMS

All the current and past cyanide monitoring has been done as and when time and resources have permitted, in addition to the regular water quality monitoring programs Steffen Robertson and Kirsten undertake. The collection of data has not been as complete as is possible, but efforts have been made to encompass the following variations in good tailings disposal (see overleaf):

- operational, recently-decommissioned and older, abandoned tailings impoundments;

- milling operations which extract uranium in addition to gold, the two elements occurring together in some of the Witwatersrand ore;

- vertical variation within the tailings mass; and

- variation in the interstitial waters in the tailings and in the associated near-surface groundwater adjacent to the tailings impoundment.

The results of the monitoring program are tabulated in the subsequent section. These data are from:

- an operational impoundment, $\pm$ 5 years in age;

- an operational impoundment, $\pm$ 10 years in age;

- a recently-decommissioned impoundment (within the last 5 years), approximately 20 years in age; and

- an abandoned dam, > 20 years in age.

The cyanide profiles through the deposited tailings are results of drilling two impoundments, both of which have been abandoned in the last ten years.

All data are for total cyanide. They were determined by using prescribed South African Bureau of Standards methods which are essentially the same as those monthly in use in North America.

CYANIDE MONITORING RESULTS

Cyanide monitoring data have been collated in five tables. These are:

- Table 1: total cyanide in the tailings system for a gold/uranium mill;

- Table 2: cyanide profile in interstitial water in a decommissioned tailings impoundment;

- Table 3: chemistry of oxidised, intermediate and reduced zones in tailings impoundments (mean values);

- Table 4: comparison of cyanide (total) in tailings impoundments and near-surface groundwater: (mean and range); and

- Table 5: comparison of total cyanide levels in near-surface groundwater with general groundwater composition.

ANALYSIS OF MONITORING DATA

The data which follow the progress of cyanides from the gold extraction plant through to the water return facility at a mill with both gold and uranium extraction facilities, given in Table 1 illustrate that disposal of tailings from such mills may not represent a cyanide pollution to water resources. While a typical total cyanide level of 9 mg/L is discharged from the gold plant, the discharge at the thickners after the uranium plant is less than 0.1 mg/L, the bulk of which is believed to be in the form of thiocyanate. The cyanide is apparently either destroyed or otherwise lost in the uranium extraction process, which may involve solvent extraction, ion exchange, precipitation or a combination of these processes. For the remainder of this passage through the disposal facility, the aqeous phase associated with the tailings reports cyanide levels less than detection at < 0.1 mg/L. In addition, there is no remobilization of cyanide, should it report to the solid phase of slurried tailings, as both the near-surface groundwater and the regional aquifer adjacent to this impoundment were found to carry levels of cyanide less than 0.1 mg/L also.

The cyanide profile with respect to interstitial waters in a gold only tailings impoundment is given in Table 2. The interstitial water is taken to be typical of any seepage which may be discharged from the base of the impoundment to the groundwater regime. Given that the cyanide levels in the tailings slurry varied between 8-19 mg/L during operations at the mill, the maximum value in the interstitial water is

now less than 3 mg/L. Therefore either the cyanide has decomposed during or after discharge, or it is being held on/in the solid phase of the tailings.

The actual cyanide profile is of interest. The upper portion of the profile to 20 m depth (66') is depleted in cyanide with values less than 0.22 mg/L. Between 20 m and 28 m (92'), the total cyanide levels increase and are in the range of 0.4-3 mg/L CN. These levels may decrease below this depth, although there is only one value of 0.16 mg/L to support such a conclusion. By comparison, the interstitial water in the sediments below this impoundment give cyanide levels less than 0.01 mg/L indicating no cyanide contamination from the impoundment.

In a second tailings impoundment, about 150 samples of interstitial water were taken from three distinct chemical zones within the tailings mass. These chemical zones - oxidised, intermediate and reduced - have been described in detail by Smith et al (1982, 1983). Table 3 illustrates the general chemistry of the three zones together with their respective total cyanide levels. These data are mean values, at least twenty samples being taken from each chemical zone.

In general, there is not a great variation in the major ion chemistry of the waters of the three zones. While the pH values are the same, the TDS and sulphate values are slightly higher in the intermediate zone and lower in the reduced zone as compared with the upper, oxidised zone. There is, however, a very clear increase in manganese levels with depth in the interstitial water coupled with antipathetic behaviour of total iron. Cyanide values then follow the major ion pattern, with highest values occurring in the intermediate zone (average value, 2.0 mg/L).

In addition, it should be noted that while the lower, reduced tailings have an interstitial water cyanide level of 0.9 mg/L, the near-surface groundwater below and adjacent to the impoundment have a mean total cyanide level of only 0.08 mg/L.

The data comparing cyanide in interstitial tailings waters with groundwater (Table 4) and cyanide in groundwater with the general groundwater chemistry (Table 5) can be considered together. Cyanide levels from the tailings examined vary from < 0.01 mg/L to about 3 mg/L with a mean value probably less than 1 mg/L. Known discharge levels for gold only mills are up to 20 mg/L and therefore the cyanide is either being destroyed prior to being held in the interstitial water within the tailings or combined with the tailings itself. Once the interstitial water is lost from the impoundment to the near-surface groundwater, it appears at levels no greater than 0.08 mg/L and, on average, less than 0.03 mg/L. Again, this may be fixation onto a solid phase or decomposition of the cyanide itself, with the addition of dilution by cyanide-free groundwater.

GENERAL DISCUSSION

From the foregoing data analysis, the following observations require some further discussion and possible explanation:

- the relatively low levels of total cyanides in interstitial tailings water, despite significantly higher cyanide discharge levels; and
- the apparent lack of contamination of the groundwater regime, even in close proximity to the impoundments.

It is suggested that there are several possible processes which may be responsible for the breakdown and/or fixation of the cyanide, removing from the aqeous system in the tailings and preventing groundwater contamination. These are:

- the method of tailings disposal: the so-called "semi- dry" or "sub-areal" disposal technique;
- the prevalent climatic conditions;
- the presence of partially or wholly oxidised iron in the tailings; and
- the presence of iron in the highly weathered, semi-lateritic or lateritic near-surface aquifer.

Sub-areal tailings disposal seeks to optimize tailings/water ratios, permitting the impoundment to be constructed by a self-build technique without the requirement of a water-retaining dam, as commonly practiced in North America. Lower water volumes on the impoundment result in smaller seepage volumes and hence limited solute transport. In addition, the presumed free cyanide-bearing tailings liquid is held in a very shallow pool on top of a dam and is readily available for interaction with available oxygen and solar radiation.

The Witwatersrand, at 2000 m (6000 ft.) in the Transvaal Highveld, has an "ideal" climate for maximizing natural cyanide oxidation; a mean yearly temperature of 15°C (60°F), in excess of 290 sunshine days per year - with only 5-10 cold days/nights, moderate but high intensity rainfall and high summer temperatures. The duration of high levels of incoming radiation resulting from the altitude and cold-free days/nights promote conditions for natural oxidation of cyanide, which are maximized by extensive area, shallow depth pool of liquid held on top of the tailings impoundment.

Pyrite, or residual pyrite, which may form between 0.5% and 5% of the tailings is subject to strong oxidation in the tailings, as evidenced by the red-brown iron minerals which form on the surface of the tailings, from the essential grey material which is deposited initially. The evidence for fixation, and hence attenuation, of cyanide by formation of iron species is documented in the literate (see discussion in Chapter 4, Huialt et al, 1983) and an active oxidation

system which is in chemical disequilibrium, such as a tailings impoundment, has significant potential for immobilization of free cyanide species from the aqeous phase.

A similar potential which exists to a limited extent is the near-surface aquifer below the tailings impoundment itself. Almost without exception, the mineralogy of this aquifer, derived from quartzitic, dolomite or shale types of strata, compromises some iron minerals. Again, this provides a mechanism for cyanide removal, attenuation and fixation.

SUMMARY

A number of observations on the dearth of cyanide contamination from cyanide bearing, gold tailings disposed on the Witwatersrand, South Africa, can be made: These are:

- despite cyanide discharge levels from gold plants of up to 20 mg/L cyanide (and perhaps significantly more), there is little available total cyanide in interstitial waters in gold tailings impoundment, the general level being about 1 mg/L;

- There is little evidence of cyanide contamination of the groundwater regime below or adjacent to gold tailings disposal facilities, the general total cyanide levels in near-surface groundwater being about 0.03 mg/L; and

- a combination of the sub-areal/semi-dry method of tailings disposal, the climate of the Witwatersrand which greatly facilitates oxidation, ultraviolet radiation involved cyanide decomposition, and the availability of iron species for cyanide complexation may be processes which contribute to cyanide reduction prior to seepage discharge to the groundwater regime.

THE CONCENTRATION OF THE COMPLEX CYANIDES IN FLOTATION TAILINGS

The factor of the concentration of complex cyanides in flotation tailings was not found in any of the Canadian or other documentation. Concentration may not have been addressed due to difficulties in assessing levels of cyanide as they occur in flotation tailings as was discussed in an earlier section.

Recent studies by the Bureau of Mines in the States, of tailings from flotation processes utilizing cyanide have been unable to find cyanides in flotation tailings. This finding may be an analytical sensitivity problem since the expected levels are extremely low. It may also be indicative of the stability of the complex cyanides...as the U.S. background study (USEPA Report No. 560/6-76-012) on cyanides stated "... the cyanide is absorbed strongly on the surface of the minerals..."

Although concentration data is absent in some key U.S. literature, other U.S. EPA documents can be used to estimate the maximum probable concentrations of cyanide in the tailings. In a U.S. EPA study (Contract No. 68-03-2552) of mineral mine operations using, or potentially using, cyanide as a depressant in flotation, the rates of usage of cyanide usage rates it is possible to calculate the maximum possible concentrations of cyanide at these surveyed plants. Table 3.1 presents a summary of those estimates.

In order to place this concentration in perspective, a complex cyanide (sodium ferrocyanide) is approved for use in table salt at a level of 13 parts per million and road salts spread on highways as deicers contain up to 350 parts per million of complex cyanides (sodium ferrocyanide and ferric ammonium ferrocyanide).

Since the cyanide used in the selective flotation process is carefully controlled by metering in weak solutions to selectively react with the surface of a small portion of the ore, it is improbable that concentrations of complex cyanides would significantly vary from

4. Suppress zinc and iron; zinc recovered due to intermittent iron suppression.

those indicated in Table 3.1. Furthermore, since some cyanides are converted in the flotation circuit by oxidation to cyanates or thiocyanates and may not report to the tailings, and due to other factors, these estimates may be somewhat high.

No reports of measurements of the level of cyanides were found in the literature. During discussions with U.S. Bureau of Mines, however, the estimate was made that possibly eighty percent of the cyanide ended up in the tailings (Ref. 3.1).

It can be calculated, however, what the maximum possible level of cyanide in the tailings is by knowing the rate at which the cyanide is added to the cell on a pounds per ton of ore basis and knowing the approximate tailings generated per ton of ore. Consideration will, however, have to be given to several other factors in common experience at flotation sites. They are:

- Intermittent use of suppressant.
- Loss of cyanide in flotation cell.
- Possibility of "overdosing" or "underdosing" reagents.
- Loss of cyanide on floated products.
- Use of suppressed minerals as products that are not blended with tailings.

FACTORS AFFECTING CYANIDE CONTENT IN TAILINGS

In the U.S. EPA's study (Ref 3.2) dealing with use of sodium cyanide in flotation, several of the mineral flotation plants studied used cyanides intermittently. This type of intermittent operation would lead to a dilution of cyanide content in tailings by discharge of non-cyanide containing wastes. Similarly, some mines add cyanide to only a portion of their flotation cells resulting in dilution proportional to the tailings generated in the treated cells as a fraction of the entire tailings (Ref. 3.3).

Cyanide will react with other flotation reagents, such as xanthate, to yield thiocyanates which do not end up in the tailings (Ref. 3.4). This loss would further reduce the calculated concentration maximum based solely on pounds of cyanide per ton of feed.

Since small amounts of cyanide are used to control flotation products (0.001 to 0.1 lb/ton) the flotation process becomes a "policeman" to determine if too much or too little suppressant is being added. As recognized in U.S. EPA's work (Ref. 3.5) the dosage of cyanides must be critically controlled to produce an acceptable product. The same argument applies for underdosing.

Some cyanide is carried out of the process with the flotation mineral product rather than the tailings. This loss would further reduce the concentration calculated on a pounds per ton of feed basis.

Tailings from one flotation circuit often become flotation products in the next flotation circuit. The cyanide preferentially reacted with the flotation product does not report to the tailings diluting the levels further.

Since feed rates of suppressant are in terms of pounds of cyanide per dry ton of ore, the water in tailings dilutes the concentration further.

PERCENT SOLIDS IN TAILINGS

With all these factors considered it is a conservative estimate to use the numbers in Table 3.1 in summary which have only been adjusted for tailings affected. Figure 3.1 shows the relative concentration of cyanide in common materials as a method of gauging the relative concentration in the flotation tailings.

FIGURE 3.1 Cyanide content of various materials.

THE ADVANTAGES OF CYANIDE

1) Cyanide for gold and silver leaching from "normal" ores requires very small doses at a relatively low concentration.
Typical concentrations in gold mill leach solutions would be 0.015-0.1% NaCN 150-1000 ppm and typical consumption would be about 1 lb/ton. Consumption can, however, be very much higher when the ore contains cyanide soluble copper minerals e.g., NGEMI 8 lb CN per ton ore consumption.

2) Cost of cyanide is relatively inexpensive at $0.40 - $0.80/lb depending on location.

3) Cyanidation yields better leach recoveries than most other lixiviants for gold and silver. The term "refractory" gold or silver ores refers to those from which the precious metals are not readily leachable by cyanide.

4) Industry is familiar with the use of cyanide and the precautions that need to be taken.

5) Cyanide is biodegradable especially in warm climates. Even if there was to be environmental impact on surface waters due to cyanide use this impact will not continue for a long period after the mine-mill shuts down - unlike acid mine drainage or seepage from sulfidic ore tailings which could persist for hundreds of years.

DISADVANTAGES OF CYANIDE

1) Cyanide also dissolves base metals and iron and these are held in solution as cyanide complexes.

2) Cyanide is toxic and does require special handling precautions. These are not difficult, however.

3) Free cyanide, some complexed cyanides and their degradation products are toxic to aquatic life at very low levels.

4) The regulations as to what levels of cyanide are permissible in effluents in the USA are not clear cut.

5) There remains some general confusion as to appropriate analytical techniques for low level cyanide in effluents and analytical interferences. There are now techniques of analysis which overcome these interferences but regulatory limits are set based on standardized analytical methods which do not include the latest improvements.

6) Comparison of toxicity data for cyanides requires careful qualification of the analytical methods used for the analysis and careful evaluation of their meaning - the problem of comparing apples and oranges exists.

7) Cyanide leaks, however small, can be sure of getting a bad press.

The Denver Post/Sunday, Sept. 23, 1984

Associated Press

Cyanide in Chicago well water

Joe Walker holds a glass of well water at his home on Chicago's far South Side Thursday after he learned that the water is tainted with cyanide. An official said Friday the source of the contamination found in two wells hasn't been pinpointed. None of the nine residents who use the wells had drunk the water, the official said. Said Walker, 'It eats my pipes up, and I know it would eat me up.'

CONTRAVERSIAL ASPECTS OF CYANIDE

1) How toxic are ferrocyanide and ferricyanide complexes or their degradation products? Should ferrocyanide be included in the cyanide level limits set for effluents? Should an analysis method be used to report total cyanide if it does not detect ferrocyanide?

2) How effective is natural degradation of cyanide in effluents in different climates?

REGULATIONS CONCERNING CYANIDE IN TAILINGS AND EFFLUENTS

Regulations governing cyanide containing effluent disposal in various gold and silver mining centers of the world have not yet been finalized. Comparison of regulated limits are complicated by the need to qualify the analytical method specified for its determination, which vary from country to country.

In some parts of the world with warm year-round climates such as South Africa and Fiji, for example, natural degradation of cyanide in solutions occurs as long as there is an adequate retention time in an impoundment. The South African drinking water standard SA Bureau of Standards second version 241 of 1971 set a recommended maximum of 0.2 mg/l CN and a maximum of 0.3 mg CN/l. The South African proposed standard for effluents in the Witwatersrand were published in government Notice No. R553 Table 2 by the Department of the Environment and set cyanide "and related components" at 0.05 mg/l.

In South Australia where gold was mined in the foothills around Adelaide, cyanidation was prohibited anywhere within the rainfall catchment area which provides the city of Adelaide with its water supply. In Brazil, individual states have set their own limits for cyanide at 0.2 mg/l. Sweden has no general fixed cyanide limits, but one operation must meet 0.5 mg free CN and has set a target of 0.2 mg/l for July, 1986.

In other parts of the world, notably North America, much more attention is focused on this aspect of gold and silver mining. In the cold northern winters, cyanide is not naturally destroyed and fisheries are much more important than in some of the other mining areas.

In general, North America has also become much more conscious of environmental protection in recent years than most other gold producing countries. Also, in parts of the USA and Canada, gold recovery plant effluent or tailings runoff does get into the river and lake water system. Considering the L50 lethal effects of cyanide in excess of 0.038 ppm on fish, and the highly developed fisheries resource of some North American inland waters, there is a clear need for responsible control of cyanide entering the inland water system. On the other hand much of the gold mining areas are in desert or semi-desert climates where there are no fisheries near the operations so there is a clear need for site specific limits which do not require unnecessary treatment costs.

Consequently, cyanide destruction techniques and disposal in mill tailings and effluents have been of major interest to the gold and silver mining industry as well as State and Federal licensing and environmental protection authorities. Unfortunately the technology for cyanide destruction in pulps and solutions and what can be acheived in operating

plant conditions was not well established. Improved analytical techniques and a better understanding of the meaning of the results are still being developed.

CYANIDE REGULATIONS

In the USA the EPA is working on a national limit for cyanide in effluents. Individual states may enforce the Federal (EPA) standard when it is fixed or may impose stricter rules on their own.

According to an EPA document "Cyanides: Ambient Water Quality Control" PB 296792 (1979), the EPA proposed an ambient quality criteria for free cyanide in effluents. To protect fresh water aquatic life, the criterion was set at 0.0014 ppm CN^- as a 24 hour average with a concentration not to exceed 0.038 ppm at any time. For the protection of human health the ambient water quality criterion is 0.0200 ppm. Federal RCRA regulations concerning effluents from leaching operations do not appear to regulate cyanide for the time being. It seems likely however, that EPA will include cyanide in the regulations they are working on for the preservation of groundwater quality.

There are four sets of Federal regulations in the USA which will ultimately be relevant to cyanide in effluents and tailings levels. Then each state has its own laws pertaining to effluent and tailings discharge or containment which are contained in the permit required to operate a mine-mill complex.

The Federal rules of consequence are:

1) NPDES regulations for discharge to surface waters, lakes and navigable waterways, rivers, etc.

2) Resources Conservation and Recovery Act RCRA governing hazardous waste disposal which have temporarily been suspended from applicability to mining and milling wastes. These are under review and will likely be reapplied to mining and milling in some form in the future. As originally promulgated, cyanidation mills for gold and silver recovery were required to be zero discharge.

3) A new set of groundwater protection laws under development by the EPA but not yet enacted.

4) The CERCLA Superfund laws under which each company that disposes of solid waste must contribute to a fund which is to be used to clean up existing threats to the environment and under which sites which lead to future environmental damage c[illegible] repaired by the government and billed to the company that caused th[illegible]

In most gold mining areas of the USA, for example in Nevada, Utah, California, Eastern Oregon, etc., the arid climate offers high evaporation rates and makes it easier to control runoff to prevent it from getting into permanent rivers and lakes. Many milling operations also are able to operate on a zero discharge basis. This is possible when the ores contain low levels of cyanide-soluble base and heavy metals. When the ores are not "clean" these species will build up in a mill that recirculates tailings water until a certain amount of solution must be bled from the circuit. In an arid climate even this should present little problem as the solutions can be evaporated so that no cyanide bearing solutions need escape to the environment. However, once cyanide salts are evaporated to dryness in a tailings pile or leached heap it may last forever because natural degradation seems to work only for solutions. It was reported that the state of California in 1981 did not accept the zero discharge concept and were insisting on cyanide destruction of cyanide in effluents even when solutions are recycled from the tailings pond. Their position may have changed since then. Homestake Mining Company's McLaughlin project will be a zero discharge operation and it is known that the state of California has insisted on double linings of the tailings pond and numerous additional measures.

In high rainfall areas, or cases such as Homestake Mining Company's Lead S. D. operations, where excess mine water and decanted tailings pond water are discharged to a creek, strict regulations governing allowable cyanide limits in the effluent are enforced.

Certainly at Noranda Grey Eagle Mines Inc. operation near the Klamath River in Northern California the determination of low levels of cyanide unexpectedly in the seepage from their tailings dam resulted in a major concern to the California Regional Water Quality Control Board and expensive mitigating action by the company even though no known environmental damage occurred. Even though rainfall exceeds precipitation at this site, it is designated for zero discharge of even treated effluent which has to be irrigated to dispose of it.

Water effluents from Homestake's Lead S. D. operation were restricted to 0.02 ppm total cyanide according to their state permit which they have worked very hard to try and meet. Judging by past penalties that have been imposed on Homestake for non-compliance, it is clear that the regulations have been enforced even before practical methods have been developed to achieve the legislated limits. This does not seem reasonable, and it was rumored that the limit may be raised to 0.08-0.10 ppm or whatever can be shown to be an environmentally acceptable level achievable with the best technology available. Homestake has been developing an in situ bioassay technique for site specific species in their effluent stream as one way of improving the monitoring of environmental toxicity of their treated effluent. This may well prove so successful as to form the basis for a modification in the way future limits are set and regulated.

At Superior Oil Company's heap leaching operation at Stibnite, Idaho, the heaps after gold has been recovered by cyanide leaching, must be rinsed to remove cyanide which is

destroyed with a hypochlorite solution. Hypochlorite is generated at the site from liquid chlorine and lime. Before tailings can be disposed of in the disposal site, free cyanide in the "off" solution must be reduced to below 0.2 ppm. When the tailings are placed on the disposal area, they are spread out in a 1 foot layer allowing further oxidation of cyanide by aeration and sunlight. Here is a case where no solutions are deliberately discharged as effluent but where cyanide destruction techniques are mandated because of the possibility of precipitation runoff from the area to a nearby tributary of the Salmon River, a sport fishing paradise. It is reputed that in Nevada, on the other hand, regulations are more easily satisfied. Nevada recognizes its dependence on the mining industry and is familiar with the use of cyanide in metallurgical processes that have been used in the state for many years without obvious damage. Zero discharge operations are often possible, and there are negligible inland fish resources near most mines that could be affected by cyanide. Even so, the Battle Mountain operation of Duval spends a lot of money chlorinating their CIP pulp discharge to the tailings area in the valley below the mine. Other operations such as at Pinson Mining Co., Freeport Gold, and many more have so far operated on a zero discharge basis.

The U.S. rgulatory situation with respect to cyanide in gold and silver mine effluents is still emerging, and it will vary from state to state.

The U.S. Environmental Protection Agency still has not issued Federal regulations regarding cyanide and thiocyanate in effluents. However, as mentioned above, regulations are likely after the impact of mining on groundwater has been evaluated. The U.S. EPA Best Practicable Technology guidelines published in 40 Federal Register 51722, November 6, 1975, under 40 CFR 440.22 indicate a maximum of 0.02 mg/l total cyanide.

The U.S. EPA is apparently shifting the regulation of mining and metallurgical effluents from a federal responsibility to a state responsibility. Each state is now formulating its own set of rules. This has resulted in a delay in the crystallization of what the final regulations are to be and a great range in the limits themselves from state to state. Each state may impose tichter limits if they wish as long as they are not less stringent than the federal limits which have yet to be announced. Because the local state regulators are inexperienced in many cases with mining waste and effluents, the result has sometimes been to demand ridiculous or ill-conceived requirements, and excessive delays in securing permits for heap leaching test projects, for example, let alone for commercial operations.

California is regarded as a trend setting state, and their emerging regulations with respect to cyanidation tailings, even for heap leaching operations, although still to be finalized, are extremely strict.

The Federal RCRA regulations concerning hazardous waste disposal have been temporarily suspended for mining waste. However, the state of California Hazardous Waste

Regulations have been enacted and in several aspects are even more strict than the Federal RCRA that is being reconsidered for mining.

The state of Washington and Montana are also said to be following California with respect to tight effluent limits and strict mine/mill operating permits.

Apart from the tightness of limits imposed on effluent discharge, a major factor in the economics of developing a new mine and mill in the USA today is the long delay required in processing permits that are required from many different regulatory authorities. Several mining companies claim that these factors are already driving investment away from mining ventures in the USA at this time.

1976), indicated that an instream value of 0.005 mg/l total cyanide would be necessary to protect fresh water aquatic life. With the available dilution ratio, this would require and effluent limitation of approximately 0.017 mg/l.

Source: EDELMAN & WALLINE

PAPUA, NEW GUINEA

Effluent from OK Tedi is discharged to a river (Tabubil?). Free cyanide levels in the river are limited by regulation to 5 ppb (0.005 ppm). There is a 200 fold dilution of effluents in the river which means that the effluent should never exceed 1 ppm.

BRAZIL

In Brazil, each state has its own effluent discharge limits. For cyanide, the limit is 0.2 ppm (not clear whether free or total cyanide).

Zn (mines only)	1.00	0.50
pH	6 to 9	6 to 9

Note: This limit is probably part of the RCRA regulations that are currently in abeyance under the Beville Amendment.

CANADIAN CYANIDE EFFLUENT REGULATIONS

In Canada, there is currently not yet a Federal limit set for cyanide in effluents, and the responsibility for developing a national standard rests with ENVIRONMENT CANADA. The levels set by ENVIRONMENT CANADA will be the basis for a minimum national standard although the individual provinces may set more stringent standards and will be responsible for enforcing the regulations.

ENVIRONMENT CANADA's mandate is to set permissable effluent limits based on what can be achieved by demonstrated technology. They are now evaluating the performance of various plant scale tests for cyanide destruction by several techniques to determine their performance. In the meantime, ENVIRONMENT CANADA has not yet set the national standard and the Provinces are permitting gold plants on a case-by-case basis. Every major new gold mill in Canada since 1980 has installed an effluent treatment plant, however. Each province has its own licensing authority which sets limits for cyanide in effluents. However in comparing these it is important to note where the sampling point is specified to be. For example in several Ontario gold operations the sampling point for effluent analysis may be 1 - 2 miles downstream from the effluent discharge point from the pond. SCOTT (1984).

In Canada, regulations affecting effluent discharge from mining and metallurgical operations are part of the Fisheries Protection Act. This gives some idea of the importance given to inland fisheries in Canada - where 37% of the world's fresh water is located.

There are still three schools of thought as to how cyanide in effluents should be controlled:

1) Free Cyanide

Free cyanide is the most available form of cyanide toxicity. However, silver and copper cyanides are also toxic. Another difficulty is that there is still much debate as to how to measure free cyanide levels.

2) Total Cyanide

Total cyanide measurements include iron cyanide which is not toxic, although it can photodecompose to yield free cyanide. This becomes more of a factor for decanted effluent flowing in shallow streams at the headwaters of major fishery rivers.

A national level set to control on the basis of total cyanide would have to be quite high because it should allow a certain amount of iron cyanide which would not be

regarded as harmful. In cases where cyanide occurs as free cyanide such a total cyanide level would probably be too high.

3) Total Cyanide & Free Cyanide

A combination of total cyanide and available cyanide standards. This would allow some iron cyanides while providing a stricter control of free cyanide and other available cyanides. For example, such a standard might end up as 0.1 ppm maximum available cyanide and 0.5 total cyanide. Such a double standard would, however, be more difficult to enforce.

Before setting any regulations, ENVIRONMENT CANADA evaluated performance by three plants employing alkaline chlorination in British Columbia and the alkaline chlorination plant at Giant Yellowknife Mines Ltd. Meanwhile three of the alkaline chlorination plants in British Columbia have been replaced by SO_2 - air cyanide removal or shut down or stopped using cyanide.

A consulting firm, namely KERR, PRIESTMAN & ASSOCIATES of Victoria, B. C., was commissioned to monitor the three alkaline chlorination plants in British Columbia and prepare a report. A summary of their report is attached hereto.

Other methods such as Inco's SO_2-Air cyanide destruction process are also being evaluated, but by 1984 the toxicity of effluents from this process had still to be quantitatively determined.

ENVIRONMENT CANADA expected to have completed the technical assessment of commercial techniques for cyanide destruction by June 1983 and the National Standard for cyanide in mine effluents was to be published no sooner than the end of 1983. However this did not materialize.

It has been pointed out that Carolin Mines Ltd. in British Columbia was shut down for a period of time in 1982 by the British Columbia Government on account of a fish kill ascribed to cyanide in their effluent. One of the requirements in the operating permit for Carolin Mines is that the water in their effluent discharge must not be toxic to fish. After retrofitting SO_2-Air in their existing system Carolin Mines stopped cyanide leaching and shipped their flotation concentrate to a smelter as dictated by a change in their ore.

ENVIRONMENT CANADA has become a center for information on cyanide measurement and on techniques for and effectiveness of cyanide destruction, in conjunction with a task force on gold mining established to include mining industry representatives. Their approach has been professional and has adopted an attitude of finding out what can be achieved within practical and economic limits. Direct contact with this organization

is an excellent source of up-to-date information far in excess of the space available here:

R: Recommended Limit
G: Goal

Motivation to Remove Cyanide from Effluents:

- To meet regulatory effluent discharge limits.

- To recover cyanide values in some instances.

The difficulty in meeting effluent regulatory limits for cyanide depends on the limits to be met, the metallurgical process employed, the nature of the ore treated, and the climate in which the operation is located, as well as the nature of the tailings impoundment.

Recovery of cyanide from effluent solutions could potentially be economically attractive in cases where very high levels of cyanide soluble metals such as copper or nickel are present in the ore which build up in level until they interfere with the process. Some cyanide recovery processes potentially make it feasible to recover cyanide, metal values and water. Although this has been accomplished on a test basis recently and on a commercial scale many years ago, no present day commercial installations are known. In very many cases cyanide is recovered by virtue of the internal recirculation and segregation of solutions within the plant or the recovery of some cyanide values in the tailings decant solutions.

TOXICITY OF CYANIDE

Cyanide is acutely toxic to fish at concentrations ranging from 0.05 - 0.1 ppm according to several researchers: HERBERT & MERKINS (1952); BURDICK et al. (1958); CAIRNS & SHEIER (1958); DOUDOROFF (1956); TURNBULL et al. (1954); LIPSCHUETZ & COOPER (1955); and WASHBURN (1948).

Industry argues that the levels that prove toxic under laboratory conditions are tested under conditions that are not representative of field conditions. In this respect the work that HOMESTAKE MINING COMPANY is currently undertaking with flow through tests should be very useful when finally published.

PROCESS REQUIREMENT

Where cyanides are to be destroyed ahead of an environmentally sensitive stream it should be borne in mind that if such a plant works perfectly for 99 plus percent of the time, then that is great. However, if it upsets only once, effluent damage would likely be as serious as if it were not installed at all - i.e., it is not average performance that counts, but the likelihood of occasional failure to meet minimum standards.

Consequently cyanide destruction plants must be reliable all the time to be useful and provision should be made for recycling of solutions that do not meet the discharge criteria during plant upsets. In this respect a continuous on-line cyanide monitoring device is under development by Witteck Development which could prove very useful if its detection limits are low enough.

MUDDER & WHITLOCK (1984) monitor thiocyanate rather than cyanide because it is more easily monitored at higher levels. They have developed an automated CNS^- monitor for use at Lead.

A second aspect to be considered, as pointed out by MUDDER & WHITLOCK (1984) is that several processes that destroy cyanide do not destroy harmful byproducts of the destruction, for example, ammonia. Nor do they remove environmentally undesirable metals such as copper, required to catalyze some cyanide destruction process. Even if ammonia is not a byproduct of cyanide destruction several mine effluents contain ammonia introduced by underground blasting. The effluent treatment process should be appropriate for the site specific conditions of climate, solution chemistry and the environment in which the plant is located.

TOXICITY EFFECTS OF CYANIDE

An enormous effort has been made to develop appropriate cyanide destruction techniques and experience is showing that the overall toxicity of the treated solution may be more important from an environmental point of view than extremely low free and total cyanide levels. MUDDER (1984) will present a paper on "Development of Site Specific Discharge Criteria through Toxicological Testing," reflecting the major efforts over several years that HOMESTAKE MINING COMPANY has put into trying to resolve cyanide effluent issues.

CHEMISTRY OF CYANIDE

The environmental behavior of cyanides as well as the performance and meaning of cyanide analyses by various analytical techniques are better understood when the chemistry of cyanide and cyanide metal complexes is understood.

Similarly the stability of various cyanide metal complexes is the basis for understanding why some complex metal cyanides are less easily decomposed than others in detoxification processes.

The chemistry of cyanides is discussed in depth by HUIATT et al. (1982), SCOTT & INGLES (1981) and MILGRAM (1984) as well as the series of INCO papers culminating with

DEVU ST, CONARD & HUDSON (1984). All of which are essential documents to anyone seriously interested in cyanide.

Some of the most fundamental tables of data describing cyanides are inserted here as a guide.

CYANIDE DESTRUCTION

Fortunately in much of the world where gold and silver are recovered by cyanidation the climate is hot or evaporation exceeds precipitation to such an extent that a zero discharge operation is possible. In hot climates natural degradation of cyanide is relied upon by producers of about 70% of the free world gold production or more. In several parts of the USA regulations for tailings disposal mandate lined tailings and evaporation ponds and zero discharge.

Cyanide destruction becomes important in climates where precipitation exceeds evaporation to the extent that a bleed to the environment cannot be avoided or where the ore treated contains so much cyanide soluble copper or nickel that the solutions cannot be recycled.

Unfortunately, the companies that must treat cyanide in their effluents, with the notable exception of Giant Yellowknife Mines Ltd. and Homestake Mining Company seldom include discussions of this important cost item in published papers describing their operations.

Prior to installation of an alkaline chlorination plant to detoxify effluent and especially tailings pulps it is highly recommended that the earlier installations be visited to learn what pitfalls can be avoided in advance.

In selecting an appropriate cyanide destruction process it is essential to perform pilot tests on actual pulps or solutions. This is impossible to simulate on a pilot scale before an actual operation that recycles solutions is brought on stream.

Several factors need to be considered when selecting such a process.

1) The effectiveness in removing CN_T^- and CN_C^- from solutions. Will it safely meet the regulated limits including ferrocyanides?

2) Does the CN^- treatment process add other toxic elements that then have to be removed by further treatment steps, e.g., Cl_2, NH_3, Cu, NH_2Cl?

3) Does the CN^- treatment process perhaps have an added advantage in removing other undesirable species such as Cu, Ni, As, etc.?

4) Can CN^- treatment be integrated in some way with an incremental resource recovery, e.g.,

- Carbon columns to destroy residual Cl_2 and recover Au?.
- Precipitate CuCN - float recovery and regeneration of CN^- for reuse?
- Recycle CN^- solutions after electro-removal of Cu.

5) Do regulations call for removal of CNS^- and CNO^-? If so, can the process achieve this?

6) Is the process upset-proof or upset-prone?

7) Is the process affordable and appropriate for operation at the proposed location?

8) Since most often it is during winter that CN removal is not helped by natural biodegradation the process performance at the operating temperatures must be considered.

TABLE 6

SOLUBILITIES OF FERROCYANIDES AND FERRICYANIDES

Name	Formula	Solubility g/l (T°C)
Ammonium Ferricyanide	$(NH_4)_3Fe(CN)_6$	very soluble
Ammonium Ferrocyanide	$(NH_4)_4Fe(CN)_6 \cdot 3H_2O$	soluble
Barium Ferrocyanide	$Ba_2Fe(CN)_6 \cdot 6H_2O$	1.7g (15°)

EFFECT OF pH ON DISSOCIATION OF HYDROGEN CYANIDE

THE NATURE OF TOXICITY OF COMPLEXED CYANIDES

IN FLOTATION TAILINGS

SUMMARY

The acute toxicity of free cyanide (molecular HCN and ionic CN^- is well documented. Free cyanide inhibits oxygen metabolism by binding to metal constituents of certain enzymes within cells. The most sensitive enzyme inhibited by free cyanide is cytochrome oxidase. When this enzyme is inactivated by free cyanide, oxygen utilization by the cells is prevented and cell death results. Cells with high oxygen demands, such as those of the Central Nervous System, are most sensitive to oxygen deprivation. Cells can detoxify low levels of free cyanide by coverting it to less toxic or nontoxic intermediates. The primary detoxification pathway is the reaction of free cyanide with thiosulfate to produce thiocyanate which is then slowly eliminated from the body in urine.

Complexed cyanides, especially those associated with flotation tailings, are generally considerably less toxic than free cyanides. However, complexed cyanides undergo varying degrees of dissociation when in solution which release free cyanide. The degree of toxicity of solutions of complexed cyanides is largely dependent upon the amount of free cyanide present. However, other factors may contribute to toxic effects as well, such as the metals themselves, e.g. copper-cyanide complexes. Whereas the level of toxicity is largely dependent on the amount of free cyanide present as a result of dissociation, the degree of dissociation for any given complex is highly variable depending on conditions. Also, for many metallocyanide complexes, no concensus exists among investigators as to the amount of dissociation under any given set of conditions because of the wide range of factors that can potentially effect the dissociation constants.

Certain complexes that are more readily dissociated in aqueous solution than iron complexes (e.g., zinc-tetracyanate, etc.) are reported as highly toxic because of the availability of free cyanide. These toxic complexed forms are not expected to be found in flotation tailings. Complexes with the cyanide group tightly bound (e.g., iron-cyanide, cobalt-cyanide) have a low toxicity and are considered nontoxic by most investigators. Copper, nickel, silver, and other metallic cyanide complexes undergo moderate degrees of dissociation relative to iron cyanides. Numerous factors affect the degree of dissociation. e.g., pH, temperature, dissolves oxygen concentration, and thus markedly influence toxicity levels.

Within flotation tailings, the more stable complexes predominate (e.g., iron-cyanides) due in part to operational practices associated with ore extraction procedures (e.g., cyanides are used to react with iron pyrites to depress them). The cyanides are frequently used to preferentially react with iron containing minerals such as pyrites to preferentially suppress them by forming iron cyanides at the surface. In the EPA reference document, The Manufacture and Use of Selected Inorganic Cyanides, page 1, the reference is made to iron complex cyanides: "Cyanide in this form is not particularly toxic nor hazardous to handle because of the great stability of the iron cyanide radical ion toward dissociation and oxidation-reduction reactions."

Inasmuch as the iron complex cyanides are more stable, thermodynamics would indicate that they would preferentially form over the less stable metal cyanides. Thus complexed cyanides associated with flotation tailings, in addition to being present in low concentrations, are relatively non-hazardous. Some complexed cyanides are used as food additives (e.g., sodium ferrocyanide). Several grams of complexed cyanide (i.e., sodium ferrocyanide) have been swallowed repeatedly by would-be suicides without apparent ill-effect. A case is reported in which disposal of cyanide wastes in a gravel pit near Cologne, Germany resulted in ground water contamination by complexed cyanide (i.e., potassium hexacyanoferrate); however, tests revealed that the complexed cyanide was relatively innocuous, so the water supply was not shut down.

There is conflicting information reported regarding the hazards associated with the iron-cyanide complexes because of their tendency to undergo photodecomposition. However, in flotation tailings, photodecomposition of iron-complexes would not produce significant amounts of free cyanide because light is not transmitted through the solid phase of the tailings. Additionally, the low concentration of iron cyanides and the fact that not all the iron cyanide would photolytically decompose at once make this degradation problem insignificant.

Complex and free cyanide appears to have an unusually low degree of chronic toxicity. The effects are either lethal or the free cyanide is detoxified by the organism. Almost no information is reported on the chronic toxicity of complexed cyanides. There is no reported evidence that cyanide is mutagenic, teratogenic, or carcinogenic. This finding is collaborated by the EPA which in March 1979 published the following statement

in their Ambient Water Quality Criteria report for Cyanide.

> "...there is no evidence that chronic exposure to cyanide results in teratogenic, mutagenic, or carcinogenic effects."

RATIONALE FOR THE ESTABLISHMENT OF ONTARIO'S PROVINCIAL WATER QUALITY OBJECTIVES

September, 1979

Ontario
Ministry of the Environment

CYANIDE

OBJECTIVE

Concentrations of free cyanide in unfiltered water samples should not exceed 5 micrograms per litre for the protection of aquatic life.

RATIONALE

Cyanide is one of the simplest and most readily formed organic compounds. Cyanide and derivatives are almost universally present where life and industry are found. Besides being very important in a number of manufacturing processes, they are found in many plants and animals as metabolic intermediates which generally are not stored for long periods to time.

Common forms of cyanide in effluents are metal cyanide complexes, hydrocyanic acid, and the free cyanide ion formed primarily from dissociated simple cyanide salts. The cyanide form present in the aquatic environment is largely pH dependent. Most of the free cyanide exists as HCN at pH values of natural waters, with the fraction increasing rapidly as the pH of the solution decreases. When simple cyanide salts dissociate in aqueous solution, the cyanide ion combines with the hydrogen ion to form hydrocyanic acid, which is highly toxic to aquatic life. Chemically, the cyanide ion behaves similarly to the halide ions -- chloride, fluoride, bromide and iodide.

The cyanide ion combines with numerous heavy metal ions to form metallocyanide complexes. The stability of these anions is highly variable. Those formed with zinc and cadmium are not stable; dissociation and production of hydrocyanic acid in near neutral or acidic environments is rapid. In turn, some of the metallocyanide anions are extremely stable. Cobaltocyanide is difficult to destroy with highly destructive acid distillation in a laboratory. The iron cyanides are also very stable but exhibit the phenomenon of photodecomposition, and in the presence of sunlight the material dissociates to release the cyanide ion, thus affecting toxicity; at night the reaction may reverse to produce a less toxic environment.

A wide variety of organic compounds may contain cyanide functional groups. These compounds belong to a class of organic chemicals called nitriles, none of which dissociates to liberate cyanide ions or molecular HCN. In addition, there are also complex organic acids, alcohols, esters, and amides that contain the cyanide radicals. These organic compounds are used for numerous products or may be a waste by-product. Their toxicity, persistence, and chemistry in the aquatic environment are not well known except for a few specific compounds.

Cyanide toxicity is essentially an inhibition of oxygen metabolism, i.e., rendering the tissues incapable of exchanging oxygen. The cyanogen compounds are true non-cumulative protoplasmic poisons (can be readily detoxified) since they arrest the activity of all forms of animal life. Cyanide shows a very specific type of toxic action. It inhibits the cytochrome oxidase system which facilitates electron transfer from reduced metabolites to molecular oxygen. The ferric iron-porphyrin molecule responsible for the catalytic action of cytochrome oxidase is the reactive site where cyanide combines with ferric (Fe(III)) iron atoms to form a reversible complex. Other enzymes containing a metal porphyrin molecule, e.g., peroxidases and xanthine oxidases, are also strongly inhibited by cyanide. Only undissociated HCN inhibits the consumption of oxygen in the tissues, causing cellular asphyxia (historic anoxia) by attaching itself to the iron of the prosthetic group of the enzyme cytochrome oxidase.

Hydrocyanic acid can be rapidly absorbed and carried in the plasma but does not combine with hemoglobin because its iron atom is divalent (ferrous). Instead, cyanide combines with methemoglobin, a mildly oxidized form of hemoglobin in which the iron atom is trivalent (ferric). Methemoglobin, which cannot carry oxygen, normally represents only a small fraction of the total hemoglobin. Since it forms an irreversible and innocuous complex with cyanide, it is an active cyanide detoxifying agent. Amyl nitrite and other agents can be used to increase the level of methemoglobin to counteract cyanide toxicity. A few of the ways in which cyanide can be metabolized within a pattern of normal physiology are by the production of thiocyanate, with amino acids, oxidation to carbon dioxide and formate, etc. The conversion of only free cyanide and not organically bound cyano groups to thiocyanate (SCN-) by action of the enzyme rhodanase is considered to be the primary method of detoxification of cyanide. Rhodanase is absent from blood and skeletal muscle, but is abundant in the liver. Thiocyanate is eliminated irregularly and slowly in the urine.

The action of cyanide on the respiration of the cell and the primary methods of detoxification of cyanide have been noted above. However, it should be pointed out that cyanide does not completely abolish cellular respiration. It is possible that a small amount of residual respiratory activity is made possibly by cytochrome-b activity, since this substance does not require the cyanide-susceptible cytochrome oxidases. An alternative explanation of residual respiratory activity of the cyanide-poisoned system is found in the action of the flavin aerobic dehydrogenases, which can transfer hydrogen to molecular oxygen without the cytochrome system.

The persistence of cyanide in water is highly variable. This variability is dependent upon the chemical form of cyanide in the water, the concentration of cyanide, and the nature of other constituents. Cyanide may be destroyed by strong oxidizing agents such as permanganates and chlorine. Chlorine is commonly used to oxidize strong cyanide solutions to produce carbon dioxide and

ammonia; if the reaction is not carried through to completion, cyanogen chlorine may remain as a residual and this material is also toxic. If the pH of the receiving waterway is acid and the stream is well aerated, gaseous hydrogen cyanide may evolve from the waterway to the atmosphere. At low concentrations or toxicity and with acclimated microflora, cyanide may be decomposed by microorganisms in both anearobic and aerobic environments or waste treatment systems.

A review of the available pertinent data on the acute toxicity of simple cyanides to fish reveals that the minimum lethal (threshold) concentrations of free cyanide from data obtained from experiments ranging from 12 minutes to 10 days with brook trout, Salvelinus fontinalis (Karsten, 1934); rainbow trout, Salmo gairdneri (Herbert and Merkens, 1952); brown trout, Salmo trutta (Burdick et al., 1958); bluegills, Lepomis macrochirus (Doudoroff et al., 1966); and fathead minnows, Pimephales promelas (Doudoroff, 1956), are reported to be 50, 70, (60 determined concentrations) 70, 104, 150 and 180 ug/L as cyanide, respectively. The minimum lethal threshold concentration is the concentration nearly or barely tolerable for individuals of average resistance when the exposure thereto is indefinitely prolonged.

Research at the University of Minnesota has revealed that the minimum lethal threshold concentrations, as determined from continuous flow bio-assays in which routine analyses for cyanide were performed, are generally lower than the above reported values. In addition, the acute data with fish indicate that, in general, juveniles are more sensitive to HCN than younger life history stages, and that their sensitivity is increased with reduction in dissolved oxygen concentration and with lowering of temperature. Over the temperature range of 25°C to 8°C the lethal threshold concentration (LTC) for juvenile bluegills (Lepomis machrochirus) was determined to decrease linearly from 130 to 58 ug/L HCN. Should the above linearity persist to lower temperature - not as yet experimentally determined - the calculated LTC values at 5, 3, and 1°C would be 41, 32 and 23 ug/L HCN respectively.

In review it can be concluded that free cyanide concentrations in the range from 50 to 100 ug/L as cyanide have proven eventually fatal to many sensitive fishes and levels much above 200 ug/L probably are rapidly fatal to most species.

Downing (1954), Cairns and Scheier (1958), and Burdick et al. (1958) have shown that the toxicity of free cyanide increases with any reductions in dissolved oxygen below the 100 percent saturation levels. Cairns and Scheier (1958) observed that even periodic lowering of dissolved oxygen decreased the tolerance of bluegills to cyanide.

Contradictory information from the literature indicates that uncertainty exists between the relationship of toxicity of simple cyanides to fish and the pH of the test solution. However, since undissociated hydrogen cyanide has been demonstrated to be the toxic cyanide species in simple cyanide solutions, changes in the pH of natural waters below a value of about 8.3 should have no measurable effect on the acute toxicity of simple cyanides to fish. There is no apparent relationship between toxicity to fish and the alkalinity and hardness of the dilution water.

Cyanide is acutely toxic to most fishes at concentrations ranging from 50 to 200 ug/L (Herbert and Merkens, 1952; Burdick et al., 1958; Cairns and Scheier, 1958; Doudoroff, 1956; Turnbull et al., 1954; Lipschuetz and Cooper, 1955; Washburn, 1948).

Some information on chronic or sublethal effects of cyanide is also available. Leduc (1966) found increased intestinal secretions in the fish, Cichlasoma bimaculatum, at concentrations as low as 20 ug/L and reduced swimming capability at concentrations of 40 ug/L. Costa (1965) reported that three common species of fish detected and avoided cyanide concentrations of 26 ug/L in approximately one hour or less. Exposure to a cyanide concentration as low as 10 ug/L reduced the swimming ability or endurance of brook trout, Salvelinus fontinalis (Neil, 1957). Growth, or food conversion efficiency of coho salmon, Oncorhynchus kisutch, was reduced at hydrogen cyanide concentrations of 20 ug/L. Small freshwater fish of the family Cichlidae exposed to a cyanide concentration of 15 ug/L lost weight more rapidly than the control fish in water free from cyanide (Leduc, 1966).

Survival and growth tests of 56 days duration on young of the yellow perch (Perca falvescens) and newly hatched bluegill fry (Lepomis machrochirus) performed at the University of Minnesota indicate that with the bluegill fry significant mortality occurred after about one month at all levels above 26 ug/L HCN. With the yellow perch, a marked effect on growth and survival was observed at about 45 ug/L, and at 64 ug/L survival was approximately 50 percent (Broderius, 1975). Chronic tests were also performed by Broderius in 1975 from egg through reproduction and into the second generation of fathead minnows (Pimephales promelas) and through reproduction and hatching with brook trout (Salvelinus fontinalis). For the fathead minnow it was observed that HCN levels above 40 ug/L decreased growth rate through 84 days.

A significant reduction in fecundity was noted at HCN levels greater than 18 ug/L. Mean percentage hatch was significantly decreased at levels of 40 ug/L HCN and higher. When the combined effect of egg production and fertility (percentage of egg hatch) were calculated at about 50, 120, 180, 250, and 330 ug/L HCN, effective reproduction was approximately 65, 59, 35, 24, and 21 percent of the controls respectively. From the brook trout chronic data, it can be calculated that at about 50, 100 and 300 ug/L HCN effective reproduction was about 80, 50, and 30 percent of the controls respectively.

Based upon chronic effects on fish growth and reproduction, an objective of 5 ug/L free cyanide as HCN is recommended.

TABLE 9

ESTIMATED CAPABILITIES OF PROCESSES FOR CYANIDE REMOVAL FROM GOLD MILL EFFLUENTS*

(Adapted from HUIATT et al. (1982) and MUDDER & WHITLOCK (1984)

a) Extra filtration step both before and after liming, if copper, nickel and ferrocyanide levels are high; requires strong acid for ferrocyanide destruction.

b) Supplementary treatment (e.g. activated carbon) if ferrocyanide level high.

c) Treatment (e.g. liming) to recover metals for disposal.

d) May require pretreatment to convert all cyanide to copper or iron complexes.

e) Depends on prior conversion to ferrocyanide.

f) Thiocyanate and ferrocyanide build-up, and water-balance considerations will necessitate bleed stream requiring further treatment.

g) Strip solution may be regenerated electrolytically, recovery in metals as powder.

h) Cyanide is recycled instead.

i) Is-20g Cl_2 is needed to decompose 1g NH_3.

j) MUDDER & WHITLOCK (1984) Pilot plant recudes CN_T to 0.35 mg/l and free CN to 0.05 mg CN/l.

k) HSA reactors reputedly in liquidation.

l) Depending on regulatory CN_T and CN limits in effluents.

m) Ferrocyanide removed only if the Prussian Blue precipitate is settled, floated or filtered from solution.

NOTE: The response "Yes" in this matrix means that there is a reaction and that levels of the metal or species referred to will be reduced. It does not necessarily mean, however, that levels can be reduced sufficiently to meet present or future permit levels or that the levels can be reduced at an affordable cost. Further discussion is provided in the text.

* The estimates of performance capability presented in this table are based on literature data for feed solutions from many different sources. The final cyanide concentration that can be achieved, and the cost of treatment in any particular case, can only be determined by actual tests.

ANALYTICAL DETERMINATION OF CYANIDES

The determination of "free" cyanide in mill solutions using silver nitrate with various indicators is well established although subject to several interferences. The most common indicator is potassium iodide but a much more convenient endpoint is obtained using 2-5 drops of 0.03% acetone solution of 5-[p(Dimethylamino)-benzylidene]-rhodanine. Cas No. 536-17-4, Eastman Kodak No. 2648. This indicator is used and recommended by Kappes, Cassiday & Associates, Reno Nevada.

The DuPont Company has developed a modification of the "free" cyanide field titration method so that it will also include copper and nickel cyanides which are environmentally undesirable. Their method involves reacting the sample first with a small amount of zinc dust to release cyanide from the copper and nickel complexed form before the silver nitrate titration which is precise down to around 1 ppm. Work is in progress to see whether this adaptation will be applicable also to the potentiometric cyanide specific electrode determination and the HACH rapid colorimetric method reportedly precise down to 0.1 ppm CN. More information will be available at the December cyanide conference in Tucson and from: Frederick W. DeVries, E. I. DuPont de Nemours & Co., Wilmington, DE.

The determination of cyanide at the very low levels of interest in tailings and effluents approaching or below regulatory limits is no straightforward matter. Several different techniques have been proposed and the literature on the subject has become somewhat confusing as illustrated when reading the exentsive literature survey on the subject by POHLANDT et al. (1983). A further complicating factor is that in making determinations of cyanide in a sample to determine whether the effluent meets a certain limit, there is not much point in using one preferred method if the limit is based on another method which is the one used by the regulatory authority. Still, if as in this case, the standard method on which a regulatory limit is based can be shown to be non-reproducible or subject to serious interferences by other species in the solution, then it becomes important to find an improved method of analysis which eventually can replace the current standard method. POHLAND (1984) described a powerful new ion chromatography method for the determination of different cyanide-metal complexes in solution.

MUDDER & WHITLOCK (1984) and MUDDER (1984) propose to overcome all argument and uncertainty by installing a site specific in situ bioassay program which would determine whether or not the effluent or treated effluent is toxic to ecological species of concern to the particular location.

The Wastewater Technology Centre in Burlington, Ontario carried out a systematic survey of methods for "free" and "total" cyanide determination in Wastewater in 1981. This review by CONN (1981) confirmed that the standard sulfuric acid distillation technique for "total" cyanide determination as it appears in the APHA-AWWA "Standard Methods" is

subject to interference by thiocyanate and sulfide. Ways to avoid this interference by simple modification of the technique have been suggested.

GRIGOROVA & LENAHAN (1983) do not believe that CNS^- interferes with the cyanide analysis but they suggest other modifications of the method to overcome interference by-sulfides.

MUDDER & WHITLOCK (1984) also undertook extensive research to evaluate and develop reliable methods for cyanide analysis and found the "total" cyanide analysis method in "Standard Methods" to be subject to interferences which could be overcome by minor modification.

If there is uncertainty about the reliability of "total cyanide" analysis, then, the uncertainty is greater when it comes to "free" cyanide or "available" cyanide analysis because then it depends very much on which metal cyanide complexes are measured and which are not, or only partially detected. This depends on the precise details of the process. One way of overcoming this would be to settle for "that free and complexed cyanide as determined by method X" based on which it is agreed by convention to determine toxicological effects and set effluent limits. A start has been made in this direction in the USA in the ASTM Methoc C determination which is gaining acceptance.

The key to understanding cyanide analysis and what results of determinations by the different techniques mean is to understand basic chemistry and in particular to understand the range in metal cyanide complex stabilities ranging from $[Cd(CN)_4]^{2-}$ with a stability constant of 10^{19} to $[Au(CN)_4]^-$ with an estimated stability constant of 10^{85} which on the table presented in HUIATT et al. (1982) in Table 7 and 10^{18} and 10^{56} respectivey by GRIGOROVA & LENAHAN (1983) in Table 8.

Tables 7 and 8 of metal cyanide stability constants as they appear in HUIATT (1982) and GRIGOROVA & LENAHAN (1983) were inserted above. It is remarkable how many discrepancies there are, nevertheless the grouping of stabilities would agree, i.e.:

Less Stable Metal Cyanide Complexes	Zinc Cyanide Cadmium Cyanide Silver Cyanide
More Stable Metal Cyanide Complexes	Ferrous, Ferric, Cupric Cyanide Complexes
Most Stable Cyanide Complexes	Gold, Nickel, Cobalt Cyanide Complexes

The less stable the complex, the easier it will be to dissociate it using acid and to distill the resulting HCN off with free cyanide for determination.

Some of the confusion about cyanide analysis is due to differences in interpretation in what should be included in the term "free" cyanide. Should it include only the species HCN and free CN^- ions, or should it include some of the various weaker cyanide metal complexes such as those of zinc, cadmium and silver, for example, and if so which ones.

It is hoped that this question will be resolved in the forseeable future. This was a topic at the 1984 Cyanide Conference to be held in December in Tucson, AZ.

TOTAL CYANIDE ANALYSIS

"Total" cyanide analysis refers to all free cyanide, HCN and all complexed cyanide including iron cyanide complexes.

APHA-AWWA & ASTM METHOD

The most commonly referred to method for "total" cyanide is that published by the American Public Health Association in "Standard Methods for the Examination of Water and Wastewater." This method is the same as the ASTM method for "total" cyanide.

This method employs decomposition of free and complexed cyanides in the presence of added magnesium chloride which catalyzes their decomposition. The liberated cyanide is quantitatively distilled off as HCN and condensed in a solution of chloramine T which converts it to cyanogen chloride. The cyanogen chloride then forms a red-blue dye on addition of a pyridine-barbituric and reagent which is quantitatively determined by photometric absorbance compared against standard solutions.

It has been found that the above method is subject to interferences:

- Sulfides are decomposed in sulfuric acid and form H_2S which is distilled with the HCN and cause a high reading.

- CNS has been found by CONN (1981) and others to give a high reading although this could not be confirmed by tests carried out by LUDZACK et al. (1954) and GRIGOROVA & LENAHAN (1983).

- MUDDER & WHITLOCK (1984) found that the above method was subject to interferences.

- GRIGOROVA & LANAHAN (1983) found that the APHA "Standard" method does not give a quantitative determination of all the iron and gold cyanide complexes present in the sample and will under read total cyanide in some samples.

Several improvements in the APHA-AWWA-ASTM method have been developed and are in use.

1) MUDDER & WHITLOCK (1984) described the use by HOMESTAKE MINING COMPANY, Lead, S. D. of the "Standard" method modified to use phosphoric acid H_3PO_4 in the place of sulfuric acid to avoid interferences. They find this technique accurate and reproducible down to total cyanide levels of 0.02 mg/l with a standard deviation of 0.01 mg/l.

2) GRIGOROVA & LANAHAN (1983) describe the use of the "Standard Method" and that prescribed by the South African Dept. of the Environment which uses $HgCl_2$ as catalyst in the place of $MgCl_2$. They find that the addition of $Cd(NO_3)_2$ at 0.5% to the sample solution ahead of acidification will prevent any sulfides from interfering by precipitating cadmium sulfide which must also be filtered ahead of acidification.

   GRIGOROVA & LANAHAN (1983) also substitute H_3PO_4 for sulfuric acid.

   GRIGOROVA & LANAHAN (1983) have shown that gold cyanide complexes which are not quantitatively determined when using the "Standard Methods" or ASTM or South African Government Gazette Method, can be quantitatively determined if zinc is added with the acid during the reflux step. However, since the use of zinc with sulfuric acid results in the generation of some H_2S which interferes with the determination as discussed above, these analysts replace sulfuric acid with phosphoric acid.

   When using zinc, however, it is found that not all the ferric cyanide complex is dissociated, so when ferrocyanide and ferricyanide are to be included in the determination as well, this method is not totally suitable.

3) According to CONN (1982 personal communication), two procedures have been tested by the Wastewater Technology Centre at Burlington, Ontario, and confirmed as reliable for determination of total cyanide in solution including iron cyanides without CNS^- interference: -

   - Distillation with HCl and hydroxylamine hydrochloride with addition of $CdCl_2$ to prevent $S^=$ distillation.

This technique was developed as a modification to the standard distillation method used in the past by KNECHTEL & CONN (1980).

- Distillation of cyanide in the presence of tartaric acid as developed by Noranda Mines Ltd., has been shown to measure total cyanide including iron cyanides and to avoid CNS^- interference. This has been confirmed by the Wastewater Technology Centre, according to CONN (1982 personal communication).

  It is believed that Homestake Mining Company determine total cyanide using phosphoric acid, which also measures iron cyanides while avoiding CNS^- interference.

In each of these cases, after distillation subsequent steps are the same as the standard technique involving conversion to cyanogen chloride CNCl by reaction with chloramine-T at a pH less than 8, followed by formation of a red-blue dye on the addition of pyridine-barbituric acid reagent. The concentration is then determined by measurement of the absorbance at 578 nm and compared against standard solutions.

The method and equipment used for the photometric step in the determination, are the same as that described in "Standard Methods for the Examination of Water and Wastewater", 14th Edition, edited by MARY ANN FRANSON and published by:-

AMERICAN PUBLIC HEALTH ASSOCIATION
1015 Eighteenth Street NW
Washington, DC 20036

The South African regulated limit refers to "cyanide and related compounds" although the method listed for their determination in the South African Government Gazette measures only "total cyanide" and then imperfectly. Clearly the South African Government intended to include complexed and free cyanide but <u>not thiocyanate and cyanate</u> in "related compounds" as was interpreted by GRIGOROVA & LENAHAN (1983).

GRIGOROVA & LENAHAN (1983) point out that thiocyanate on acidification is converted to ammonia and is not reported in the "total cyanide" analysis:

$$2NaCNO + H_2SO_4 + 4H_2O = (NH_4)_2\ SO_4 + 2NaHCO_3$$

GRIGOROVA & LENAHAN (1983) do not find that thiocyanate interferes with cyanide analysis. They refer to a test by LUDZACK, F. J.; MOORE, W. A. and RUCHHOFT, C. C. (1954) in which thiocyanate and cyanate were refluxed for two hours in a cyanide blank solution without yielding any reading for cyanide. Since their work was dated 1954 long before there was an interest in cyanide determination at current ppb levels, possibly these authors were testing interference at a much higher detection limit for cyanide, and

the tests should be redone. That a low level interference might occur was also indicated by CLYSTERS & ADAMS (date unknown).

WEAK ACID DISSOCIABLE CYANIDE

The ASTM Procedure D-2036-81 Method C is gaining ground at least in the USA for determination of free and metal complexed cyanides with the exception of iron complexed cyanides, as a means of determining toxic cyanide levels.

The ASTM Method C has been found to give satisfactory detection limits, accuracy and precision and to be free of significant interferences when applied on Homestake effluent solution according to WHITLOCK & MUDDER (1984).

ASTM METHOD C

This method uses acetic acid and sodium acetate buffered at pH 4.5 and zinc acetate for the dissociation of metal cyanide complexes. Apart from this detail the method is believed to be identical to the "Standard Methods" technique.

There are numerous other techniques for analyzing cyanide. For example, PALMER & SKARSET (1981) described the Determination of Free Cyanide using a Microdiffusion Technique followed by a Pyridine-barbituric Acid Photometric Finish. This measures HCN, CN^- and cyanide in weak cyanide complexes such as cadmium, lead, manganese and zinc cyanide.

Complexes of copper, iron, nickel and silver are not dissociated into free cyanide at the microdiffusion at pH 7. Cyanate, sulfide and thiocyanate do not interfere and the method is claimed to be sensitive down to 5 ppb with a standard deviation of less than 10%.

The caustic solution containing CN^- is neutralized with acid phosphate solution and chloramine T is added to oxidize CN^- to CNCl which reacts with pyridine and then with barbituric acid to form a purple dye whose wavelength of maximum absorbance is 580 nm.

Full color development takes 12 minutes after addition of pyridine-barbituric acid solution and the color is stable for 50 minutes. Calibration curves are linear to 0.3 ppm.

As and when regulations on allowable limits on cyanide in effluents emerge, they will also have to specify how the cyanide analyses are to be carried out.

INCO METHOD FOR CYANIDE ANALYSIS

Inco uses three techniques for cyanide determination in conjunction with their cyanide destruction method.

1) Analysis of total cyanide by distillation of an acidified sample in the presence of HCl - hydroxylamine hydrochloride as described by CONN (1981). This technique is used for periodic check analyses.

2) Picric acid addition and spectrophotometric analysis determination of the weak acid dissociated cyanide measures free cyanide, HCN and cyanide associated with Ni, Cu, Zinc, etc. The only complexed cyanide not measured is that occuring as a complex with iron and cobalt. This method is described by ZATKA (1980).

   Before carrying out this analysis calcium is added to precipitate excess $SO_3^=$ as $CaSO_3$ otherwise $SO_3^=$ forms a color compound with the picric acid, which gives a positive photometric response. The calcium is added to the solution until no more $CaSO_4$ is precipitated and the picric acid is added to the supernatant solution, which gives a normal color development. This takes a few minutes to develop.

   When there is $SO_3^=$ present in solution, a color forms immediately the picric acid is added, which gives a clue to the presence of the interference.

3) Total iron in solution is analysed by AA. There are 6 moles of cyanide per mole of Fe analyzed. In terms of ppm by weight, this means that for each ppm of Fe analyzed there will be close to 3 ppm of cyanide as iron cyanide.

   The cyanide as iron cyanide determined by method 3 added to weak acid dissociated acid by method 2 give total cyanide by easy to analyze techniques. The sum of these two results invariably correspond well to total cyanide determined by method 1 described by CONN (1981).

In reviewing the finer points for selection of analytical techniques for cyanide determination at these levels, it is helpful to call on the advice of others who have been evaluating the processes for years:

THE DETERMINATION OF CYANIDE IN WATERS

by B. Grigorova and W. Lennhan

Cyanide is a toxic substance. That is neither a masterpiece of understatement nor the utterance of an idiot. The fact is (and it is in facts that, as scientists, we are supposed to deal) that the toxicity of cyanide is no greater than that of many substances commonly, and casually, used, with little or no thought to their toxicity. Many indeed are subjects of jokes; such as hydrogen sulphide, the toxicity of which is similar to that of hydrogen cyanide. Nobody but a homocidal, or suicidal, maniac would dream of mischievously planting a "bomb" to produce the stink of bitter almonds. The word cyanide has about it a dread mystique. More than any other word it conjures up spectres of death. It is the stuff that bad dreams are made on.

And yet cyanide is an essential reagent in many technological processes: in the metallurgical industry, especially in the metallurgy of gold, it is of particular importance. Indeed it is more than doubtful if the Witwatersrand would ever have achieved its spectacular potential had it not been for the discovery of the cyanide process.

And yet, again, despite its popularity as a poison and its scientific significance; the chemistry of cyanide seems to have been, until recently, somewhat superficially understood. Paradoxically, perhaps, the reason can be found in the spectacularity of its effectiveness in all aspects of its application.

Furthermore, both the simplicity of techniques by which its metallurgical application can be controlled and the dread with which its deathly attribute is abhorred have led to a confusion, and even to a misuse of elementary terminology. This is probably the most serious single problem in the analytical chemistry of cyanide.

The Metallurgist talks of "free" and "total" cyanide when he really means "free" and "total available" cyanide. The Environmentalist talks of "total" cyanides (or "cyanide and related compounds") while he need only interest himself in cyanide and <u>some</u> of its complexes. The Analytical Chemist strives, as is his custom, to satisfy all his clients.

In the context of this symposium however, we must obviously confine ourselves to the environmental aspects of the problem. And, as we see them, these aspects, apart from the procedures which we shall discuss, are three-fold:

1) All official regulations, of which we are aware, demand the specification of "total" cyanide in water and effluent; yet we are unaware of any method by which true total cyanide can be determined.

2) All but one of the metallo cyanide complexes (cobalt) can be determined by techniques to be described in this presentation; yet officially prescribed methods are generally less effective: neither the procedure authorized by the South African Department of the Environment nor that of the American Public Health Association is capable of effecting complete dissociation of the iron and gold cyanide complexes.

3) Many of the cyanide complexes are so stable that their toxicity is negligible. Thus it is not only the terminology that is questionable: one wonders if the results derived by the official analytical procedures constitute a valid measure of the toxicity of the water or effl-

Be that as it may, the practicing environmental chemist is committed to the analytical control of the environment, and to principles embodied or implied in the relevant legislation. But it is the wise chemist who knows his own terminology. And he would be well advised to be wiser still; and to ensure that terms such as "total" appear, in his report, within the security of quotation marks.

THE DETERMINATION OF CYANIDES IN THE HYDROMETALLURGICAL PROCESSING OF GOLD

by

C. POHLANDT

The determination of cyanides in cyanidation processes is of considerable importance for several reasons.
For example, excessive consumption of the reagent must be prevented for economic reasons; the chemistry of the process must be controlled for efficient operation; and, most important of all, environmental pollution must be avoided. Depending on the pH value of a solution, cyanide can be present as the molecular acid (HCN), as ionic cyanide, or as metal complexes of widely varying stability. Classical methods for the determination of cyanide are invariably tedious and time-consuming, and are rarely suitable for the rapid analysis of large numbers of samples.

Ion chromatography has gained increasing acceptance in the determination of a large variety of anions and, with an amperometric instead of a conductivity detector, it is eminently suitable for the determination of cyanides[1]. For the determination of 'free' or 'available' cyanide, the sample simply needs to be diluted and to be injected into the chromatographic system. With a weakly alkaline mobile phase containing ethylene diamine, excellent separation of the cyanide from most other anions, including common interferents such as sulfide and thiocyanide, is obtained. The method is fast, precise, and reasonably accurate, and as little as 50 µg of cyanide ion per litre can be

---

Cyanide and the Environment Conference, University of Arizona. Dec. 1984

reliably determined. Weak metal cyanide complexes, for example those of cadmium, zinc, and nickel, are decomposed in the alkaline environment of the chromatographic system, whereas strong cyanide complexes, for example those of iron, gold, and cobalt, remain intact and are retained on the anion-exchange separator.

'Total Cyanide'

The determination of 'total' cyanide requires the decomposition of strong metal cyanide complexes. Classical methods of determination require boiling under reflux with acids, usually followed by a distillation step. At the Council for Mintek Technology (Mintek) it was considered that an attractive alternative approach would be to combine ultraviolet irradiation, which results in the photo-ionization of strong cyanide complexes, with the ion-chromatographic procedure. It was established that, in 3 per cent hypophosphorous acid (50 per cent), all the metal cyanide complexes except that of cobalt decompose completely if they are irradiated for 2 to 3 minutes. Various mercury lamps were tested as irradiation sources. Those with a maximum radiation output at wavelengths longer than 300 nm were preferred because thiocyanate was not decomposed, whereas the recovery of cyanide from the hexacyano cobaltate complex improved. It was established also that a more powerful lamp, i.e. a 400 W instead of the 100 W mercury lamp originally used, further improved the decomposition of the cobalt complex (i.e. 50 per cent), and 96 to 100 per cent of the cyanide present was reproducibly recovered from a mixture of stable complexes. Photo-ionization is complex, and the oxidation-reduction reactions involved need to be carefully controlled if

reliable analytical results are to be obtained. For example, the irradiation of an aqueous solution of ionic cyanide in the absence of reducing agents results in the quantitative formation of harmless cyanate within 3 minutes. Metal complexes, on the other hand, decompose slowly with the simultaneous appearance of cyanide and cyanate ions. Therefore, pollution of the environment with so-called 'stable' cyanide complexes must be avoided, since irradiation by sunlight would result in the continuous production of small amounts of cyanide over long periods of time, which could be harmful to marine life.

Individual Cyanide Complexes

Recently the Dionex Corporation, U.S.A., issued a series of application notes describing the separation of the complexes of cobalt from gold (I) and gold (III), and also the separation of iron (II) from iron (III) by mobile-phase ion chromatography (MPIC)[2]. This procedure utilizes the principles of ion-pair chromatography, and uses a suppressor device to reduce the conductivity of the mobile phase prior to conductimetric detection.

Metallurgical processes that involve the use of resins or carbons frequently suffer from the 'poisoning' of such materials by, for example, metal cyanide species that cannot be eluted under normal stripping conditions. It follows that a knowledge of the kind of complexes present in the system is of considerable importance.

A method based on the information issued by Dionex has been developed that enables the cyanide complexes of copper, nickel, cobalt, iron (III) or iron (II), and gold to be separated (Figure 1). The determination of the

FIGURE 1. The separation of five individual metal cyanide complexes

copper complex that, due to decomposition in the suppressor, could not be detected conductimetrically, was achieved by simultaneous photometric detection at 240 nm. Calibration graphs for the various complexes were found to be linear over the concentration ranges 0.2 to 10 $mg.l^{-1}$; the gold (I) complex was the least sensitive. The separation of the two iron complexes, as claimed by the Dionex Corporation, could not be verified under any experimental conditions. Iron (II) and iron (III) cyanides were found to decompose rapidly when exposed to daylight, and additional peaks due to decomposition products were observed in the chromatogram. Daylight also had a pronounced effect on the hexacyano cobaltate (III) complex, resulting in the formation of the aquo-pentacyano cobaltate (III) complex. Since it is the latter complex that was previously identified[3] as causing resin poisoning, it is of significance that the proposed procedure is able to distinguish between the two cobalt complexes.

DETERMINATION OF CYANIDES IN DRINKING AND NATURAL WATERS, AND INDUSTRIAL EFFLUENTS

Cyanide has long been know to man for its toxicity. Although that fact, cyanides are widely used in the mining, electroplating, steel, gas, food and many other industries. It is not surprising, therefore, that the cyanide content, often is high in effluents and in the atmosphere.

Before we go any further on the subject, lets distinguish the different forms in which cyanide may appear.

Cyanide, depending on the pH value, occurs as molecular hydrocyanic acid (HCN), cyanide ions (CN^-), metal cyanides ($M(CN)_x$) which are sparingly soluble in water, but form a variety of highly soluble alkali-metallic cyanide complexes in the presence of alkali cyanides. The alkali-metallic cyanides can be expressed by the formula: $AyM(CN)_2$, where A represents the alkali, M represents the heavy metal (copper, cobalt, cadmium, nickel, iron, gold, silver, zinc, etc.) x is equal to the valence of A taken y times, plus the balance of the heavy metal. The initial dissociation of these soluble alkali-metallic cyanides is expressed by the equation (I):

$$A_yM(CN)_x \longrightarrow yA \quad + \quad M(CN)_x^{y-}$$

Depending on several factors, pH being one of them, the dissociation can continue with liberation of the CN^- radical and consequent formation of the highly toxic hydrogen cyanide (HCN).

In the aqueous solutions, therefore, there are cyanide radicals (CN^-), hydrocyanic acid (HCN) and metallo-cyanic radical $(M(CN)_x^{y-}$.

In analytical chemistry we discuss the terms "free" and "total" cyanide.

"Free" cyanide represents the content in solution of the hydrocyanic acid (HCN), the simple alkali cyanides (NaCN or KCN) and some unstable alkali-metallic cyanides, such as $Na_2Zn(CN)_4$ and $Na_2Cd(CN)_4$.

The term "total" includes that mentioned above plus all metallo-cyanide complexes.

The extreme toxicity to human and equatic life, of the molecular hydrogen cyanide (HCN), formed in solutions of cyanides, by the hydrolytic reaction of CN^- radical with water is well known.

Although metallo-cyanide complexes are undoubtedly far less toxic, than the CN^- ions and the molecular hydrogen cyanide, it is possible, that under certain conditions, CN^- ion liberates from these complexes. They are, therefore, a potential hazard and as such, they must be subject to a careful determination and elimination from the effluent waters.

Depending on their stability constant and pH values, metallo-cyanide complexes tend to ionize and convert to the toxic form of cyanide ion or hydrogen cyanide. The zinc and cadmium complexes are totally dissociated in strong alkaline solutions, as well as in any ordinary pH in natural waters. They can be considered, therefore, as acutely toxic.

The increasing stability of some metallo-cyanide complexes is expressed in Table I.

TABLE I

THE INCREASING STABILITY OF SOME METALLOCYANIDE COMPLEXES

Metal (M)	Complex ((M-CN)	Stability Constant Ka
Zn^{2+}	$Zu\ (CN)_4^{2-}$	10^{17}
Cd^{2+}	$Cd\ (CN)_4^{2-}$	10^{18}
Ag^{1+}	$Ag\ (CN)_2^{1-}$	10^{20}
Fe^{2+}	$Fe\ (CN)_6^{4-}$	10^{24}
Cu^{2+}	$Cu\ (CN)_4^{2-}$	10^{25}
Fe^{3+}	$Fe\ (CN)_6^{3-}$	10^{31}
Au^{1+}	$Au\ (CN)_2^{1-}$	10^{28}
Ni^{2+}	$Ni\ (CN)_4^{2-}$	10^{41}
Au^{3+}	$Au\ (CN)_4^{1-}$	10^{56}
Co^{3+}	$Co\ (CN)_6^{3-}$	10^{64}

The stability constant of hydrogen cyanide in aqueous solutions is (II):-

$$Ka = 4,93 \times 10^{-10}$$

Bearing in mind the extreme toxicity of cyanide and the behaviour of the complex cyanides, it can easily be understood, why the waters for domestic supply and the effluent waters from mines and industries are subject to stringent regulation of their cyanide content. By the South African standard regulations, the recommended limit of cyanide concentration in waters used for domestic purpose is 0,01 mg/L as CN^- and the maximum permissible level is 0,2 mg/L as CN^-, for the industrial effluents, the level of "cyanides and related compounds" is max. 0,5 mg/L as CN^- by the government regulations. The toxic level for fish is 0,03 mg/L CN^-.

It seems to be a lack of recognition of the fact that relatively innocuous compounds are counted in the official methods of analysis.

The regulations must, however, be based on the knowledge of cyanide chemistry and stability of the metallo-cyanide complexes. Regulations based on the simplistic idea, that all cyanides are dangerous, are economically damaging and should be challenged.

For example, the acute toxicity to fish of diluted solutions containing copper or silver cyanide complexes is due mainly or entirely to the toxicity of the undissociated ions. Another paradoxal fact is that the use of sodium ferrous-cyanide ($Na_4Fe(CN)_6 \cdot 10H_2O$) is permitted in food industry as anti-caking agent, and in the same time the analtyical chemist strives to find the most satisfying method to obtain the ferro-cyanide contained in the sample.

The extreme stability of the iron-cyanide complexes in a natural environment is also a well known fact; their photo-decomposition is very low in deep, turbed and shaded waters and the loss of the hydrogen cyanide to atmosphere and its bacterial and chemical destruction, prevents the increase of HCN concentration in waters to harmful levels, practically classifying them as non-toxic.

There is another controversial fact: by the Government Regulations, the permissible level in industrial effluents is for "cyanide and related compounds", but the method suggested by the S.A. Government Gazette and the American Public Health Association do not determine them. The content of thiocyanates (SCN^-) and cyanate (CNO^-) is very limited, and the toxic dose level for KSCN is 760 mg/kg or 76 times lower than the cyanide toxicity.

On acidification, CNO^- will be converted to ammonia, according to the reaction (III).

$$2NaCNO + H_2SO_4 + 4H_2O \longrightarrow (NH_4)_2SO_4 + 2NaHCO_3$$

On the thiocyanate role in the cyanide determinations, there are two controversial opinions.

Some authors are suggesting, that thiocyanate interferes with the analysis of cyanide.

The second opinion on this subject, which incidentally is the opinion of the authors of this paper, is that thiocyanate does not interfere.

In their work "Determination of cyanides in water and waste samples", Ludzack, Moore and Ruchhof show that thiocyanate (SCN^-) and cyanate (CNO^-) do not interfere with the determination of "total" cyanide. In the experiment performed by them, a 500 mg/L of KSCN and KCNO respectively were added to the distillation flask and refluxed for 2 hours following the cyanide determination procedure. The results reported in both tests were "NIL" cyanide (CN^-) concentration in mg/L.

Clysters and Adams in their work "Potentiometric determination with the silver sulphide membrane electrode", show that thiocyanate only at very high concentrations of 1 per cent will interfere with the direct reading of cyanide containing solutions; in other words the determination of "free" cyanide. Thiocyanate at this level (1 per cent) does not occur in any fresh natural waters or industrial effluent.

A test on the effect of the thiocyanate on the cyanide determination was performed at AARL.

Three 50 ml portions of potassium auro-cyanide standard solution, with cyanide concentration of 100 mg/L CN^-, were mixed with different volumes of potassium thiocyanate standard solution, with thiocyanate content of 100 mg/L SCN^-.

The solutions were refluxed for two hours, following the modified cyanide distillation procedure, suggested by AARL.

The results obtained, are expressed in Table II:-

TABLE II

EFFECT OF THIOCYANATE ON THE CYANIDE DETERMINATION

Thiocyanate Concentration in the Analysed Solution as SCN^- (mg/L)	Cyanide Concentration as CN^- (mg/L)	
	Added to the analysed solution	Obtained after distillation
50	100	93
67	100	91
80	100	100

From the results in Table II, it can be observed, that thiocyanate in concentration up to 80 mg/L SCN^- does not interfere with the "total" cyanide determination.

A really disturbing interference on cyanide determinations, "free" and "total", occur when sulphides (S^{2-}) are present in the analyte.

In most instances, the distillation procedure eliminates the interferences, but, when sulphide is present in the solution to be analysed, it is distilled as hydrogen sulphide gas (H_2S), which interfere with the following analytical procedure, ion-selective electrode measurement, or argomtometric titration.

Sulphide also converts the cyanide to thiocyanate, the reaction greatly accelerated at elevated pH value.

Removal of sulphides, as soon as the sample is collected, and before its stabilisation with sodium hydroxide, therefore, is essential.

A 0,5 solution of cadmium nitrate $Cd(NO_3)_2$ is added to precipitate the sulphide. The yellow precipitate of cadmium sulphide (CdS) that forms is filtered. The complete precipitation of sulphide is tested with lead acetate paper.

An excess of cadmium nitrate should be avoided, to prevent the possibility of formation of additional cyanide complexes.

Historically, the generally accepted treatment of cyanide containing industrial and mine effluents, is by alkaline chlorination (Reaction IV):

$$CN^- + Cl_2 \xrightarrow[>9,0]{pH} CNCl + NaCl$$

The first product of the chlorination is highly toxic cyanogen chloride (CNCl), but in alkaline media, the reaction proceeds by hydrolysation of the cyanogen chloride to the cyanate ion (CNO^-) which has a very limited toxicity (Reaction V):

$$CNCl + 2NaOH \longrightarrow NaCNO + NaCl + N_2O$$

The chlorination process is relatively fast, but depends greatly on dissociation of the cyanide complexes.

Metal cyanide complexes, such as cobalt, gold, iron and nickel do not dissociate to any degree. The chlorination process, therefore, does not eliminate their presence but their resistance to chlorination and lack of toxicity, overlap.

As many cyanides are unstable under certain conditions, the cyanide determinations should be performed on receipt of the sample. If this is not possible, the sample should be treated immediately for sulphide elimination, followed by addition of sodium hydroxide to raise the pH value to 12,0.

Bottle with sample must be kept in a dark, cool place.

A holding time of 24 hours only, is recommended.

The high toxicity of "free" cyanide for animals and human beings, together with its wide spread industrial application creates a need for a sensitive and selective method, capable of detecting cyanide concentrations at the 0,01 mg/L level.

The relatively stable metallo-cyanide complexes, although not showing typical cyanide toxic properties, are still potentially dangerous and classified by most health organisations together with the toxic form of cyanide.

An application of a very sensitive method for their analysis, therefore, is essential.

From the discussion on cyanide toxicity and the health regulations on drinking waters and industrial and mine effluents, it is obvious, that a procedure for determination of the "total" cyanide concentration in water samples should be employed. And yet, the method suggested by the Government Gazette and the American Public Health Association, cannot ensure the complete decomposition and therefore, determination of auro-cyanide, cobalt-cyanide and ferric-cyanide.

In the "Annual Book of ASTM Standards", part 31, Water, edition 1981, published by the American Society for Testing and Materials, the following statement can be found:-

"The cyanide in some cyano-complexes of transition metals: that is cobalt, gold and platinum is not completely determined by these methods".

The method suggested by the American Society for Testing and Materials is the same, as the one described by the American Public Health Association. The procedure proposed by the South African Government Gazette is very similar to the American Standard Methods.

They consist of one hour reflux of the analyte with sulphuric acid and catalyst to help the dissociation of the metal complexes.

The APHA suggests the use of magnesium chloride ($MgCl_2$) as a catalyst, which is very effective on the iron complexes dissociation.

The S.A. Government Gazette uses the same method and includes mercuric chloride ($HgCl_2$) as the catalyst, and a longer reflux time.

Both procedures fail to decompose completely the gold, cobalt and iron cyanide complexes, an event that can be observed from Table III:-

TABLE III

THE RECOVERY OF SOME STABLE METALLO-CYANIDE COMPLEXES AFTER DISTILLATION PROCEDURE SUGGESTED BY THE S.A. BUREAU OF STANDARDS AND THE AMERICAN PUBLIC HEALTH ASSOCIATION

Metal complex	Cyanide Concentration as CN^- (mg/L)	Recovery of the Cyanide as CN^- (%)
$K_4Fe(CN)_6$	100	88,9
$K_3Fe(CN)_6$	100	82,6
$KAu(CN)_2$	100	49,1
$K_3Co(CN)_6$	100	20,3

The accurate detection of the auro-cyanide complex, if not of great importance for the American environment, is of major interest to the South African society. Due to the gold mining industry, the South African effluents contain a significant amount of gold cyanide complexes. An accurate method for their detection is, therefore, essential.

As the existing procedures yield unsatisfactory results, work to solve this problem was undertaken in AARL.

A modification of the reflux-distillation procedure was established with excellent results for the determination of the auro-cyanide complex. A 100% recovery of potassium auro-cyanide $KAu(CN)_2$ was achieved.

The procedure involves two hours reflux of the cyanide complex solution, with ortho-phosphoric acid and addition of zinc powder to the known catalysts ($MgCl_2$ and $HgCl_2$).

Some of the data obtained by application of this modified technique, can be observed from Table IV.

TABLE IV

THE RECOVERY OF GOLD-CYANIDE COMPLEX AFTER DISTILLATION PROCEDURE SUGGESTED BY ANGLO AMERICAN RESEARCH LABORATORIES

Analyte	Cyanide Concentration present as CN^- (mg/L)	Mean of cyanide Concentration obtained as CN^- (mg/L)	Recovery of Cyanide conc. (%)
$KAu(CN)_2$	1000	1000,66	100,07
$KAu(CN)_2$	100	100,84	100,84
$KAu(CN)_2$	80	80,18	100,22
$KAu(CN)_2$	25	25,40	102,40

This technique was used for analysis of metallurgical plant samples, which explains the high concentration of auro-cyanide in the solutions used for the test.

The replacement of sulphuric acid with ortho-phosphoric acid was essential to prevent its eventual reduction, when zinc powder as catalyst is used. This can evolve hydrogen sulphide which is absorbed, together with the hydrogen cyanide, in the alkaline solution.

A test to observe this event was performed. Results obtained are expressed in Table (V):-

TABLE V

THE POSITIVE INTERFERENCE OF SULPHURIC ACID, ON CYANIDE DETERMINATION, WHEN THE Zn REDUCTION PROCEDURE IS INVOLVED

Type of mineral acid used for distillation	Recovery of the cyanide concentration as CN^- (%)
H_2SO_4	102,3
H_3PO_4	100,5

As the hydrogen sulphide interferes in positive way, higher results, when sulphuric acid is used, were obtained.

The second reason for replacing the sulphuric acid was based on suggestion made by Serfass, Freeman, Dodge and Zabban, that sulphuric acid reflux procedures yield better results when iron-cyanide complexes are included in the analyte.

Once, the auro-cyanide complex problem was solved, as it can be expected in science, a new problem arose. Zinc salts render the iron cyanide complexes insoluble, therefore it is possible, that the zinc powser will act as anti-catalyst with respect to the iron-cyanide complexes.

An experiment was performed which confirmed our fears. Work to overcome this new problem is proceeding, but the data is still not sufficient, to draw a final conclusion. Anyhow it is certain, that a prolonged reflux-distillation procedure, for the dissociation of iron-cyanide complexes is essential.

There are three different techniques for determination of the cyanide content after the digestion procedure: argentometric titration suitable for concentrations higher than 10 mg/L CN^-, the spectrophotometric method and ion-selective electrode procedure for low cyanide concentrations.

There are a few advantages of the ISE procedure to the spectrophotometric method:

1. When the colourimetric method is employed, the cyanide from the solution reacts with chloramine-T to form the very toxic gas cyanogen chloride (CNCl). Its toxicity exceeds greatly that of the cyanide.

2. When colour measurement is performed, the 8-15 minutes interval for absorbance reading is critical. Even with a specified time of 8-15 min., there is a slight change in absorbance (standard methods for the Examination of Waters and Waste Waters; APHA, AWWA, WPCF).

3. Ion-selective electrode measurement is fast with good accuracy and precision. Sixty to eighty cyanide determinations per day can be performed, when the computerised Phillips PW 9416 Ion-Selective Analyser is used.

4. No previous knowledge of the cyanide concentration, of the sample to be analysed is necessary when ISE and the standard addition procedure is used; as it covers a very wide concentration range from 0,01 up to 100 mg/L CN^-.

The ISE procedure has advantages also to the argentometric titration method, when "free" cyanide is analysed and p-dimethylaminobenzylidenerhodanine is used; which incidently is the best available indicator for cyanide determination.

The interferences of copper (Cu) on titrimetric determination was investigated at AARL. It was found, that the argentometric method can tolerate the present of 1,5 mg Cu only, in the solution to be analysed. Copper and other heavy metals do not effect the ISE procedure.

At this stage of investigation on the chemistry of the metallo-cyanide complexes, we still cannot suggest a procedure which will ensure the dissociation of all possible metallo-cyanide complexes.

The analytical chemist still faces the dilemma for the right choice of decomposition technique for cyanide complexes. A knowledge of the type of the solution to be analysed, for indication of the probable existance of certain metallo-cyanide complexes, as well as knowedge of the behaviour of those complexes under the digestion conditions, are the answers to the problem.

CYANIDE
(Colorimetric–Chloramine-T, Pyridine-Pyrazolone)

1. Scope and Application

1.1. This method is applicable to the determination of cyanide in surface, waste and sea water. When the distillation assembly described is used the method is sensitive to about 2 μg/L.

2. Principle and Theory

2.1. Distillation of the sample in the presence of sulphuric acid converts complex cyanides into hydrocyanic acid, HCN. The HCN gas is absorbed in a solution of sodium hydroxide and the cyanide is determined colorimetrically.

Equations:

$$Fe(CN)_6^{4-} + 6H^+ \longrightarrow 6HCN + Fe^{2+}$$

$$HCN + NaOH \longrightarrow NaCN + H_2O$$

2.2. In the colorimetric measurement, the cyanide in the sodium hydroxide solution after distillation is converted to cyanogen chloride, CNCl, by reaction with chloramine-T, $CH_3C_6H_4SO_2NClNa \cdot 3H_2O$. The CNCl then forms a blue dye on the addition of pyridine-pyrazolone ($C_{10}H_{10}N_2O$) reagent and the absorbance is measured at 620 nm.

The reaction may be expressed by the following equations (ref. 11.4):

3. Interferences

3.1. Sulphides interfere and should be removed prior to distillation (see section 5).

3.2. Other interfering substances are removed by distillation.

4. Sampling Procedure and Storage

4.1. The sample should be collected in a 2-L plastic bottle and analyzed as soon as possible after collection.

4.2. Samples should be preserved by addition of sufficient NaOH to raise the pH to 11.0 or above, and be stored in a cool place.

5. Sample Preparation

5.1. Decant a sample aliquot for distillation.

5.2. Sulphide is removed by treating the alkaline sample at pH 11.0 with small increments of powdered lead carbonate, $PbCO_3$. Black lead sulphide precipitates in samples containing sulphide. Repeat this operation until no more lead sulphide forms. Filter and rinse the precipitate, add the rinse water to the filtrate, and use an aliquot for analysis. Avoid a large excess of lead

carbonate and a long period of contact in order to minimize complexing or occlusion of the cyanide with the precipitated material.

6. Apparatus

6.1. A 1000-mL three-necked flask fitted with ground-glass joints; to the three necks are fitted a thistle funnel which extends below the liquid level, an air sparging tube drawn to a fine tip, and a Friedrichs condenser (Fig. 1).

6.2. Heating mantle.

6.3. Magnetic stirrer-plate and stirring bar.

6.4. Gas absorption column made from Pyrex tubing, 22 mm I.D. and 450 mm long, filled with glass helices (3 mm I.D.) (Fig. 1).

6.5. Technicon proportioning pump fitted with 8 pumping tubes, 2.8 mm I.D.

6.6. A 100-mL graduated cylinder mounted with clamp on a retort stand so that its position can be adjusted.

6.7. Spectrophotometer for use at 620 nm, providing a light path of 1 cm.

7. Reagents

7.1. Sodium hydroxide solution, 1 N: Dissolve 50 g sodium hydroxide, NaOH, in 1 L distilled water.

7.2. Mercuric chloride solution: Dissolve 34 g mercuric chloride, $HgCl_2$, in 500 mL distilled water. (Caution: Toxic; take care to avoid ingestion.)

7.3. Magnesium chloride solution: Dissolve 51 g magnesium chloride, $MgCl_2 \cdot 6H_2O$, in 100 mL distilled water.

7.4. Sulphuric acid, H_2SO_4, concentrated.

7.5. Sodium hydroxide solution, 0.2 N: Dissolve 8 g sodium hydroxide, NaOH, in 1 L distilled water.

7.6. Acetic acid, CH_3COOH, conc. and 1 + 4.

7.7. Stock cyanide solution: Dissolve 2.51 g potassium cyanide, KCN, in 1 L water. Standardize with 0.0192 N silver nitrate, $AgNO_3$. The solution loses strength gradually and must be rechecked every week. Approximate strength, 1 mL = 1 mg CN. (Caution: Toxic; take care to avoid ingestion.)

7.8. Standard cyanide solution: Dilute 10 mL stock cyanide solution to 1 L with distilled water; mix and make a second dilution of 10 mL to 100 mL. 1.00 mL = 1.0 μg CN. This solution must be prepared daily. (Caution: Toxic; take care to avoid ingestion.)

7.9. Chloramine-T solution: Dissolve 1 g of chloramine-T, $CH_3C_6H_4SO_2NClNa \cdot 3H_2O$, in 100 mL water. Prepare daily.

7.10. 1-Phenyl-3-methyl-5-pyrazolone solution: Prepare a saturated aqueous solution (approximately 0.5 g/100 mL) by adding the pyrazolone, $C_{10}H_{10}N_2O$, to water at approximately 75°C. Agitate occasionally as the solution cools to room temperature. If necessary, the pyrazolone (melting point 127°C to 128°C) can be purified by recrystallization from ethyl alcohol. Usually this is not required.

7.11. Pyridine, C_5H_5N.

7.12. Bis-pyrazolone (3,3'-dimethyl-1,1'-diphenyl-{4,4'-bi-2 pyrazoline}-5,5' dione).

7.13. Mixed pyridine-pyrazolone reagent: Mix 125 mL of the filtered, saturated aqueous solution of pyrazolone with a filtered solution containing 0.025 g bis-pyrazolone dissolved in 25 mL pyridine. Several minutes of mixing is usually necessary to dissolve the bis-pyrazolone in pyridine. The mixed reagent develops a pink colour on standing, but if used within 24 h this does not affect the colour production with cyanide. Prepare daily.

7.14. Standard silver nitrate solution: Dissolve 3.27 g of silver nitrate, $AgNO_3$, in 1 L of distilled water. Store in a dark bottle. One millilitre of this solution is equivalent to 1.00 mg CN.

8. Procedure

8.1. Procedure for distillation.

8.1.1. Close pinch clamp (Fig. 1).

8.1.2. Add about 80 mL of water to the graduated cylinder and adjust the position of the cylinder so that the tube dips near the bottom of the cylinder.

8.1.3. Add 750 mL sample to the flask; insert stirring bar, and start the stirrer.

8.1.4. Add 50 mL 1 N NaOH solution (7.1) to the 250-mL beaker and start the pump.

8.1.5. When the absorption column is wet with NaOH solution, add 20 mL mercuric chloride solution (7.2) and 10 mL magnesium chloride solution (7.3) through the thistle tube.

8.1.6. Slowly add 37 mL concentrated sulphuric acid to the flask through the thistle tube.

8.1.7. Turn on the heating mantle and allow the contents of the flask to boil vigorously (Excess air as the flask heats up will escape from the equipment through the dip tube in the graduated cylinder).

8.1.8. After 1 h of boiling turn off the heating mantle and open pinch clamp.

8.1.9. Remove the tube pumping NaOH from the NaOH solution; rinse the contents of the column into the NaOH beaker by pumping approximately 150 mL distilled water through the absorption column and collect in the NaOH beaker.

8.1.10. Transfer quantitatively to a 250-mL volumetric flask and make up to the mark.

8.2. Procedure for colorimetric measurement.

8.2.1. Transfer 15 mL of distillate to a 50-mL beaker.

8.2.2. To prepare standard solutions for the calibration curve, use cyanide standard 1 mL = 1 μg CN. Pipette 0 (blank), 0.2 mL, 0.5 mL, 0.8 mL and 1.0 mL into 50-mL beakers and make up to 15 mL with NaOH, 0.2 N (7.5). Proceed with 8.2.3, treating samples and standards in the same manner.

8.2.3. Adjust pH to 6-7 with 1 + 4 acetic acid. Transfer to 25-mL volumetric flask.

8.2.4. Add 0.2 mL chloramine-T solution (7.9) and mix. Allow 1-2 min for the reaction.

8.2.5. Add 5.0 mL mixed pyridine-pyrazolone reagent (7.13) and make up to the mark; mix. Allow 20 min for colour development.

8.2.6. Read absorbance at 620 nm in a 1-cm cell.

8.2.7. As a check on the distillation step, periodically process cyanide standard solutions through the complete procedure.

9. Calculations

9.1. Prepare a calibration curve derived from the peak heights obtained with the standard solutions.

9.2. Determine the micrograms of cyanide in the samples by comparing sample peak heights with the calibration graph.

9.3. Calculate the cyanide concentration as follows:

$$\text{mg/L CN} = \frac{F \times D}{C \times E}$$

where E = cyanide determined (μg),
D = diluted absorbing solution (mL),
C = original sample (mL), and
E = aliquot used (mL).

10. Precision and Accuracy

10.1. No data available.

Figure 1. Cyanide distillation apparatus

1. Scope and Application

1.1. This method is applicable to the determination of cyanide in water and wastewaters in the range from 0.001 mg/L to 0.100 mg/L HCN.

1.2. The detection limit for this method is 0.001 mg/L CN^-.

2. Principle and Theory

2.1. Complex cyanides are converted to hydrocyanic acid, HCN, by irradiation with ultraviolet light. After irradiation the sample is distilled from phosphoric acid solution into a sodium acetate absorbing solution.

2.2. In the colorimetric measurement, the cyanide in sodium acetate solution is converted to cyanogen chloride, CNCl, by reaction with chloramine-T. The CNCl then forms a blue dye on the addition of pyridine-pyrazolone reagent, and the absorbance is measured at 620 nm.

2.3. Equations:

The reaction may be expressed by the following equations (ref. 11.3):

3. Interferences

3.1. Sulphides interfere and should be removed prior to analysis (see section 5).

3.2. Thiocyanate gives an apparent total cyanide on an equimolar basis.

3.3. Some organic cyanide compounds such as nitriles are decomposed under test conditions.

3.4. Other interfering substances are removed in the distillation step.

4. Sampling Procedure and Storage

4.1. The sample should be collected in a 125-mL plastic bottle and analyzed as soon as possible after collection.

4.2. Samples should be preserved by addition of sufficient NaOH to raise the pH to 11. Usually 1 mL of 10% sodium hydroxide solution per 100-mL sample is adequate.

5. Sample Preparation

5.1. If sulphide is present, decant a 100-mL aliquot of sample and add 0.5 g citric acid and 0.5 g sodium bisulphite, $NaHSO_3$. Stir the solution and allow to stand for 15 min. Decant the supernatant from the precipitated sulphur and neutralize the excess sulphite with hydrogen peroxide (30%), using starch-iodide paper as an indicator. Then immediately treat the sample aliquot with sodium hydroxide solution to raise the pH to above 10.

5.2. Treat samples containing free chlorine with sodium bisulphite using starch-iodide paper as an indicator.

6. Apparatus

6.1. Technicon AutoAnalyzer unit consisting of:

6.1.1. Manifold (Fig. 1).

6.1.2. Recorder.

6.1.3. Sampler.

6.1.4. Colorimeter equipped with 50-mm flow cell and 620-nm filters.

6.2. Proportioning pump, Carlo-Erba model 1512/20.

6.3. UV reactor. The coil consists of quartz tubing, 3 mm I.D. and 12 m long, wound to a diameter of 13 cm. A 400-W mercury lamp is used. For description of the reactor, see the "Nitrogen: Organic" (automated ultraviolet digestion) method.

6.4. Distillation equipment (see Fig. 2). The distillation column consists of borosilicate glass tubing, 12 mm I.D. and 350 mm long, wrapped with 22-gauge heating wire to give a resistance of about 24 ohms. Approximately 65 V ac is applied to the heating wire using a variable transformer.

6.5. Gas absorption column. For details of construction, see Figure 3.

7. Reagents

7.1. Stock cyanide solution, 1000 mg/L as CN: Dissolve 2.51 g potassium cyanide, KCN, in distilled water. Add 10 mL of 10% sodium hydroxide solution (7.2) and make up to 1 L in a volumetric flask. Standardize with 0.0192 N silver nitrate solution using indicator solution (7.4). The solution gradually loses strength and must be rechecked every 2 weeks. (Caution: Toxic; take care to avoid ingestion.)

7.2. Sodium hydroxide solution, 10%: Dissolve 100 g sodium hydroxide, NaOH, in approximately 750 mL distilled water and make up to 1 L.

7.3. Standard silver nitrate solution, 0.0192 N: Dissolve 3.270 g silver nitrate, $AgNO_3$, in distilled water and dilute to 1 L in a volumetric flask (1 mL of this solution is equivalent to 1 mg CN).

7.4. Indicator solution: Dissolve 0.02 g rhodanine (p-dimethylaminobenzylidene) in 100 mL acetone.

7.5. Intermediate cyanide solution, 10 mg/L as CN: Dilute 10 mL stock cyanide solution (7.1) and 10 mL sodium hydroxide solution (7.2) to 1 L with distilled water.

7.6. Standard cyanide solution, 0.1 mg/L as CN: Dilute 10 mL intermediate cyanide solution (7.5) and 10 mL sodium hydroxide solution (7.2) to 1 L with distilled water.

7.7. Working cyanide standards: Prepare a series of standards to cover the required concentration range by appropriate dilutions of the standard cyanide solution (7.6). All standards should be preserved with sodium hydroxide solution at the rate of 1 mL of 10% NaOH per 100 mL solution.

7.8. Phosphoric acid solution: Dilute reagent grade o-phosphoric acid, H_3PO_4, with an equal volume of distilled water.

7.9. Hypophosphorous acid solution: Dilute 50% hypophosphorous acid, $H(H_2PO_2)$, with an equal volume of distilled water.

7.10. Sodium acetate solution, 2%: Dissolve 20 g sodium acetate, CH_3COONa, in distilled water and make up to 1 L. Adjust the pH of this solution to 6.5 with acetic acid (glacial).

7.11. Wash solution, 0.1% sodium hydroxide solution: Dilute 20 mL of 10% sodium hydroxide solution (7.2) to 2 L with distilled water.

7.12. Mixed pyridine-pyrazolone solution: Dissolve 0.75 g 3-methyl-1-phenyl-2-pyrazolin-5-one and 0.05 g 3,3'-dimethyl-1,1'-diphenyl-(4,4'-bi-2-pyrazoline)-5,5'-dione in 50 mL pyridine. Add 250 mL distilled water and mix. Prepare daily.

7.13. Chloramine-T solution: Dissolve 1 g chloramine-T, $CH_3C_6H_4SO_2NClNa \cdot 3H_2O$, in 100 mL distilled water. Prepare daily.

8. Procedure

8.1. Set the system in operation and allow to warm up.

8.2. Determine the rate of distillation by measuring the volume of liquid that overflows from each of the two U-tube traps. Adjust the power to the distillation column heater so that approximately 20% of the liquid is being vaporized in the tube.

8.3. Check to see that the conical joint at the top of the gas absorber column is filled with sodium acetate solution.

8.4. Run sodium hydroxide-treated standards and samples at 20 per hour.

9. Calculations

9.1. Prepare a calibration curve from the peak heights obtained with the standard solutions.

9.2. Determine the concentration of cyanide in the samples by comparing sample peak heights with the calibration curve.

10. Precision and Accuracy

10.1. In a single laboratory (Water Quality Branch), a natural water sample was analyzed and the coefficient of variation at a level of 0.023 mg/L was ±3.8%. The same sample was spiked with 0.025 mg/L cyanide and the mean concentration found was 0.046 mg/L with a coefficient of variation of ±2.2%. The average percent recovery was 94%.

10.2. The recoveries of standard solutions of complex cyanides were compared with the recoveries of simple cyanide standard solutions (KCN).

Complex cyanide	Recovery (%)
Potassium hexacyanocobaltate	78–80
Potassium tetracyanonickelate	75–80
Potassium ferrocyanide	95–100
Potassium ferricyanide	95–100

CYANIDE ANALYSIS OF MINING EFFLUENTS BY SPECIFIC ION ELECTRODE

Robert H. Mann, Barbara J. Hayes

Radian Corporation
8501 MoPac Blvd.
Austin, Texas 78758

Abstract. The Ag/S specific ion electrode has been evaluated for analysis of both free and total cyanide. Metal cyanide solutions were prepared from reagent grade compounds and by stoichiometric mixture of the metal with a potassium cyanide solution. Solutions containing Cu^{+1}, Ni^{+2}, Fe^{+2}, Fe^{+3}, and Zn^{+2} complexes were analyzed prior to and following EDTA pretreatment. This effort provides an understanding of the effect of each metal cyanide complex on the SIE analysis of free and "total" cyanide.

Background

Efforts to treat mining wastes and effluents to reduce total cyanide levels must be based on both the concentration of cyanide and forms in which cyanide are present. The recognized reflux distillation method with columetric measurement for total cyanide as cited by EPA (1979), ASTM (1977), and Standard Methods (1975) is both time consuming and tedious. It also requires a well-trained and experienced analyst to insure that precise data are obtained. Total cyanide results and their use have been questioned when defining the cyanide toxicity of water streams containing stable complex-metal cyanides. Although metal cyanide complexes are considered inert, questions have been raised concerning their decomposition by UV light in aquatic streams.

The specific ion electrode method for analysis of free cyanide has been previously reported by Frant (1972) and Riseman (1972) and Schluster (1976). An EDTA pretreatment has been presented by Frant to chelate metals from dissociated metal cyanide complexes and therefore allow measurement of their cyanide counterpart as free cyanide. Schluster (1976) evaluated the use of the cyanide specific electrode for determining free and total cyanide of metal cyanide solutions. That effort indicated the CN electrode responds to free cyanide only and not to that complexed to metals. The objective of this study was not to determine stability of complexed metal cyanides, however, the information obtained may be used as a crude comparison.

Study Description

The method used in this study was based on the studies previously performed and published by Frant (1972) and Riseman (1972). The method utilizes the silver/sulfide electrode which is capable of measuring the activity of the silver ion down to a 10^{-20}M concentration. An indicator/buffer containing silver cyanide complex is added to the sample. The complex is in equilibrium with silver and cyanide ions as shown in equation 1:

$$Ag(CN)_2^- \rightleftharpoons Ag^+ + 2CN^- \qquad (1)$$

As the complex is added to a solution containing cyanide ion, cyanide shifts the equilibrium to the left. For increased cyanide concentrations, the silver ion activity decreases and is observed as a more negative electrode potential. Because the silver cyanide complex requires two cyanide ions for each silver ion, a 118mv decrease will be observed for each tenfold increase in cyanide. This gives twice the slope observed when using a monovalent anion electrode and allows for greater measurement precision.

Riseman noted that the pH of the solutions must be adjusted to at least 11 to convert 98 percent of the cyanide to ionic form. Also, samples and standards should have about the same ionic background. For this study, the ionic background of the standards was adjusted to be consistent with the expected ionic strength of process effluents from the mining industry. This was done by the addition of sodium hydroxide to a 0.5M concentration. This was also more than adequate to raise the pH above 11.

Apparatus

The apparatus used in this study was an Orion Model 701A digital pH/mV meter equipped with an Orion 90-02 double junction reference electrode and an Orion 94-16 silver/sulfide electrode.

Reagents

Electrode Filling Solutions: The Orion filling solutions supplied with the double junction reference electrode were used to fill its inner and outer chambers.

Indicator/Buffer: 17.5g of reagent grade disodium hydrogen phosphate (Na_2HPO_4) were dissolved in approximately 80 mls of deionized water. The solution was stirred for 30 minutes before the addition of 2.2g of sodium hydroxide (NaOH) and 0.1g of silver potassium cyanide ($KAg(CN)_2$). The solution was diluted to a final volume of 100 mls. This solution was checked daily before use and was discarded when any precipitate was noticed.

Stock Cyanide Solution: Two grams of sodium hydroxide (NaOH) was dissolved in about 800 mls of deionized water and 2.51g of potassium cyanide was added before final dilution to one liter. This solution was standardized weekly by potentiometric titration using silver nitrate.

Working Cyanide Solution: The standardized stock cyanide solution was diluted daily as appropriate to give a 100 mg/l working standard.

Silver Nitrate Standard: 3.265g of crushed and dried (40°C) silver nitrate ($AgNO_3$) was dissolved in deionized water and diluted to one liter (1 ml = 1 mg CN^-).

25M Sodium Hydroxide: 200g of sodium hydroxide pellets were dissolved in 200 mls of deionized water.

0.1M EDTA: 3.36 g of the disodium salt of EDTA was dissolved in deionized water and diluted to 100 mls.

Acetic Acid: Reagent grade concentrated glacial acetic acid.

Metal Cyanide Complexes: 100 mg/l solutions (as cyanide) of nickel, zinc, copper, ferric- and

ferro- cyanide complexes were prepared by direct weighing from purchased reagent grades compounds. The composition of each of these compounds is listed in Table 1.

In addition 10 mg/ℓ CN solutions of nickel and zinc cyanide complexes were prepared by the stoichiometric mixture of each metal and potassium cyanide solutions.

Specific Ion Electrode Measurements

The following steps were used for all measurements in this study:

- a 100 ml sample was pipetted into a 150 ml glass beaker,
- 2 ml of 25N sodium hydroxide were added to adjust the pH and ionic background,
- 2 ml of silver cyanide indicator/buffer were added,
- the electrodes were immersed in the sample and the solution was stirred at a low rate on a magnetic stirrer,
- the millivolt reading was observed over a five minute period on the relative millivolt scale before recording the final millivolt reading, and
- the electrodes were rinsed with deionized water and blotted dry prior to the next sample measurement.

Broad Range Standard Calibration Curve

A standard calibration curve was prepared using potassium cyanide solutions over a broad range of concentrations from 50 mg/ℓ down to 0.01 mg/ℓ. The measurements were made in both increasing and decreasing order of concentrations and were repeated on three separate days to determine the reproducibility of the standard curve. At the 95 percent confidence level the standard deviation of all measurements was ± 8mV. Figure 1 presents the broad range calibration curve. Nernstian response is identified from 50.0 to 0.25 ppm cyanide. Readings were reproducible down to 0.01 ppm cyanide, however, the response differential per tenfold change in concentration dramatically dropped at the 0.25 ppm level.

A shorter range standard calibration curve (1.0 to 0.02 mg/ℓ) was also run on a daily basis to determine the concentrations of the metal cyanide complexes.

Determination of Total Cyanide

Total cyanide determinations required that the samples be pretreated to release the cyanide from the metal complexes prior to measurement as the free cyanide ion. This release was accomplished as follows:

- acetic acid was added to lower the pH to 4,
- 1 ml of 0.1M EDTA was added,
- the solution was heated at 50°C for five minutes on a water bath, and
- the solution was cooled to room temperature.

Following pretreatment, the cyanide concentration was determined as described for free cyanide under specific ion electrode measurements.

Determination of Free Cyanide

Free cyanide was determined on each of the metal cyanide complexes by the method previously described. Each complex was diluted to give theoretical cyanide concentrations of 1.0, 0.5, 0.1, 0.05 and 0.02 mg/ℓ. The millivolt reading was used to determine the free cyanide concentration by comparison to the short range standard curve prepared on the day of the determination.

Results and Discussion

The results of the evaluation of the silver/sulfide electrode for the analysis of free and/or total cyanide are given and discussed in the following paragraphs. The results will be given in three parts:

- reproducibility of the method when applied to potassium cyanide standards,
- the measurement of free cyanide in metal cyanide complexes, and
- the measurement of total cyanide in metal cyanide complexes.

Reproducibility of Method

The reproducibility of the silver/sulfide electrode method for the analysis of cyanide was determined by preparing low range free cyanide calibration curves using solutions of potassium cyanide. Table 2 presents the response of the Ag/S electrode to free cyanide. Tests were performed in duplicate on eight days to define the reproducibility of the standard curve. At the 95 percent confidence level mV response is reproducible to ± 9mV. The relative standard deviation is 16 percent at concentrations above 0.25 ppm. The low range calibration curve (Figure 2) again shows linearity down to 0.25 ppm.

Results of Free Cyanide Measurements

The results of the free cyanide determinations are given in Table 3. This table presents the concentration of ionic cyanide (free) for each of the metal cyanide complexes tested. Zinc and nickel results include analysis of the metal cyanide compound and the stoichiometric mixture of free cyanide with the metals. The agreement between both methods of complex generation is fairly good and support one another. Data indicate that at the 1.0 and 0.5 mg/ℓ concentrations the percent free cyanide found by this method varies from less than 10 percent free cyanide for nickel complexes, to 20-30 percent for copper complexes, to 100 percent for zinc

complexes. These data follow anticipated trends since copper and nickel are known to form stable complexes with cyanide while the complex formed with zinc is relatively unstable. The zinc complex appears so loosely bound that the addition of sodium hydroxide for pH/ionic background adjustments breaks up the zinc cyanide complex to form the more stable zinc hydroxide complex. Therefore, this method will not only measure free cyanide but may include along with zinc, other unstable metal cyanide complexes. No detectable free cyanide was observed from either iron complex.

Figure 3 presents the results for free cyanide observed in metal cyanide complex solutions.

Results of the Total Cyanide Measurements

The results of the total cyanide measurements are given in Table 4. The EDTA pretreatment will release part of the cyanide complexed by nickel and copper but will not release that complexed by iron.

A comparison of the diluted compounds indicates greater dissociation for the nickel complex, followed by zinc, and finally copper (Figure 4). Of particular interest is the apparent decrease of cyanide from the zinc complex when subjected to the EDTA treatment when compared with that without treatment.

Discussion

Copper, nickel and zinc results in Figures 5 through 7, provide a visual interpretation of both precision and recovery. Shaded areas on the graphs represent the 95 percent confidence interval of results for free and total cyanide.

The narrow bands for free cyanide for copper and zinc indicate a better reproducibility of results. In comparison wider bands for total cyanide also include greater imprecision due to the added steps in the procedure. Free cyanide for the nickel complex (Figure 6) was quite low and, therefore, a greater band is presented at the detection limit.

To further evaluate loss of cyanide from zinc complexes during the EDTA pretreatment two additional experiments were performed. Both cyanide and metal cyanide complexes were again reanalyzed following EDTA pretreatment. The timing of sodium hydroxide addition after EDTA pretreatment was investigated. Results of this experiment provided additional information concerning recovery. There appears to be no appreciable loss of free cyanide that is related to the EDTA pretreatment itself. An observed loss seems to occur when addition of sodium hydroxide is delayed. When original evaluations were made, solutions were allowed to cool 30-40 minutes prior to sodium hydroxide addition. This delay was consistent in all tests. When additional experiments were performed, approximately 55 percent of free cyanide was lost with a 30 minute delay of NaOH addition. No loss was observed upon immediate addition.

Experimental results of copper, nickel and zinc complexes are tested in Table 5. They do not follow a consistent trend. Both copper and zinc complexes exhibit greater recovery of total cyanide with immediate pH adjustment following the EDTA treatment. However, nickel results are lower with immediate addition. No explanation is made at this time concerning the nickel results. However, no conclusion can be made which is applicable to all metal cyanide complexes concerning cyanide loss.

Conclusions

The results of the evaluation of the silver/sulfide specific ion electrode for the analysis of cyanide have demonstrated the following:

- The method is reproducible and linear in the concentration range from 50.0 to 0.10 mg/l cyanide when using solutions of potassium cyanide.
- For free cyanide analysis, the more unstable metal cyanide complexes such as zinc cyanide decompose to cyanide ion when treated with sodium hydroxide for pH and ionic background adjustment.
- For total cyanide analysis, not all metal cyanide complexes quantitatively decompose to cyanide ion by the EDTA treatment.

Therefore, the specific ion electrode method may be useful for the measurement of the chemically reactive cyanides which include free cyanide plus the easily dissociable complexes such as zinc cyanide. For total cyanide determinations, the method is less useful under the current EPA definition of the parameter since the iron cyanide complexes are not measured by this method.

AN OVERVIEW OF CYANIDE TREATMENT METHODS FOR GOLD MILL EFFLUENTS

by
James S. Scott

INTRODUCTION

Both the technical and patent literature describe a multitude of processes for the destruction or recovery of free cyanide and cyanide-metal complexes from solutions. Included among these are: natural degradation, evaporation, alkaline chlorination, oxidation with sulphur dioxide-air, biodegradation, oxidation with hydrogen peroxide, adsorption on ferrous sulphide, acidification-volatilization, ozonation, ion exchange, chemical precipitation, electrochemical, reverse osmosis, ion flotation, adsorption on activated carbon, electrodialysis, high pressure oxidation, photolysis and polymerization (1,2,3). Even this lengthy list will not include all proposed methods. A number of these methods have been suggested as being applicable to the treatment of gold mill wastewaters.

My purpose today is not to discuss all these methods since in most cases they have been rejected as either technically or economically unacceptable for the treatment of gold mill effluents, particularly in view of the availability more practical processes. Instead, I will limit my remarks to those methods currently in operation at gold mills. These methods are listed in Table 1.

TABLE 1 METHODS IN PRACTICE FOR THE TREATMENT OF GOLD MILL WASTEWATERS

Used at several mills:	Used at one mill:
Natural degradation	Biological
Evaporation	Oxidation with hydrogen peroxide
Alkaline chlorination	Adsorption on ferrous sulphide
Inco SO_2-air	Acidification

Environment Canada

In the further course of this conference a number of speakers will be addressing in depth several of these processes and therefore, I will limit my remarks regarding their subjects. One process on which I will comment in a little more detail is that of alkaline chlorination. I have two reasons for this; one, it is not to be described in a separate paper and two, Environment Canada has completed an extensive evaluation of the full scale performance of this method at four gold mills.

My remarks today stem principally from my experience in Canada since being a Canadian, this is the area in which I have the greatest familiarity. It also appears to be the country in which the greatest variety of chemical methods for the destruction of cyanides is being employed.

GOLD CYANIDATION PROCESS

Before discussing the treatment of gold mill waste effluents I would like to first briefly review the origin and characteristics of these wastewaters.

The common process for the recovery of gold from lode gold deposits is that of cyanidation, in which gold is leached from the ore in a weak cyanide solution, usually NaCN. Although there are a number of variations in gold mill flowsheets, the feed to most cyanidation circuits is finely ground ore.

A simplified flowsheet for the conventional gold milling process is shown in Figure 1. This illustrates the cyanidation process in which the gold is recovered from solution by precipitation with zinc dust, i.e., the Merrill-Crowe process. The overall chemical equation representing the dissolution of gold is:

$$4Au + 8NaCN + O_2 + 2H_2O \longrightarrow 4NaAu(CN)_2 + 4NaOH$$

To recover the gold, the solution is first separated from the leached solids, usually by filtration, then deaerated and the gold precipitated by the addition of zinc dust. The precipitation step is represented by the equation:

$$2NaAu(CN)_2 + Zn \longrightarrow Na_2Zn(CN)_4 + 2Au$$

The gold precipitate is smelted for the production of gold bullion.

A large proportion of the barren (gold free) solution is recirculated to cyanidation to take advantage of its remaining leaching potential for gold. However, it is necessary to bleed off a portion of this solution from the mill to avoid the build-up of deleterious metals, i.e., copper, iron, nickel, zinc, arsenic and antimony which dissolve simultaneously with gold, and would subsequently interfere

with the further dissolution and precipitation of gold. The extent to which barren solution must be discarded is related to the mineralogy of ore.

Some barren solution is used to wash, usually on filters, any gold bearing solution from the leached solids. In some mills the solids are given an additional wash with fresh water to remove the remaining cyanide before the solids are pumped to the tailings impoundment area. The importance of adequate washing with fresh water at this stage to avoid the escape of cyanide cannot be over-emphasized for those mills which practice the treatment of barren bleed directly. The release of cyanide in improperly washed filter cake can be appreciable. Some mill operators claim not to discharge barren solutions but in these cases, although this may not be done directly, barren solution is discarded as moisture with the leached solids filter cake (4).

A relatively recent innovation in gold milling is the carbon-in-pulp (CIP) process by which gold is recovered directly from the leach slurry. In the CIP process gold is recovered by adsorption on activated carbon directly from the cyanidation pulp in agitated tanks following cyanidation. The gold laden carbon is separated from the tailings slurry by screening. The slurry, either treated or untreated for cyanide removal, is then discharged to a tailings impoundment area. Gold is recovered from the carbon, usually by stripping with hot caustic cyanide solution and by electrowinning from the strip solution. Most of the newer gold mills employ the less costly carbon-in-pulp process.

The CIP process introduces two important considerations with regard to cyanide destruction; first, the amount of cyanide discharged from the mill and second, the form of the effluent containing the cyanide. Since there is no recycle of cyanide in this process, a greater amount of cyanide is contained in the mill discharge than with the Merrill-Crowe process. Also the cyanide discharged is contained in a slurry rather than in a clear liquid.

CYANIDE IN GOLD MILL DISCHARGES

In selecting a method for cyanide removal it is important to recognize the forms and stabilities of the cyanides which are present in the waste effluents. Cyanide is not a solvent entirely specific to gold and therefore, depending upon the mineralogical composition of the gold ore, the waste effluents discharged from a mill contain a wide variety of cyanide species. These species have been classified into 5 general categories as indicated in Table 2. In this Table, the cyanide-metal complexes are listed in order of increasing stability from top to bottom. The stabilities of these compounds are important in selecting a cyanide removal method since their stabilities can affect both the kinetics of treatment processes and the applicability of certain methods for removing cyanide.

TABLE 2 RELATIVE STABILITY OF CYANIDE COMPLEXES

TERMS	FORMS OF CYANIDE
1. Free Cyanide	CN^-, HCN
2. Simple Compounds	
a) readily soluble	NaCN, KCN, $Ca(CN)_2$, $Mg(CN)_2$
b) relatively insoluble	$Zn(CN)_2$, $Cd(CN)_2$, CuCN, $Ni(CN)_2$, AgCN
3. Weak Complexes	$Zn(CN)_4^{2-}$, $Cd(CN)_3^-$, $Cd(CN)_4^{2-}$
4. Moderately Strong Complexes	$Cu(CN)_2^-$, $Cu(CN)_3^{2-}$, $Ni(CN)_4^{2-}$, $Ag(CN)_2^-$
5. Strong Complexes	$Fe(CN)_6^{4-}$, $Co(CN)_6^{4-}$

In addition to the many cyanide complexes, mill solutions often contain appreciable amounts of thiocyanate and thiosalts. These compounds are of particular importance since their presence requires additional reagent in most oxidation type cyanide destruction processes.

Waste barren solutions can be discharged from mills as solutions per se, or as moisture with filtered leached tailings or in tailings slurries from a CIP circuit. The compositions of waste barren solutions vary considerably as shown in Table 3.

TABLE 3 ANALYSES OF TYPICAL WASTE BARREN SOLUTIONS FROM GOLD MILLS (MG/L)

CN_T	*CN_W	CNS	Cu	Fe	Ni	Pb	Zn

* CN_W - Weak acid dissociable cyanide by ASTM Method-C, i.e., cyanides less stable than iron cyanide.

The underlined figures indicate ranges of concentrations.

Through natural processes and dilution in tailings impoundments the concentrations of pollutants in mill wastewaters are reduced considerably but seldom to desired levels for discharge to the environment. The analyses of effluents discharged from several gold mill tailings ponds are given in Table 4.

TABLE 4 ANALYSES OF TYPICAL TAILING POND EFFLUENTS (MG/L)

* In this Table LT_{50} refers to the exposure time at which 50% of the test fish died in 100% effluent.

TREATMENT PROCESSES FOR GOLD MILL EFFLUENTS

Until 3 or 4 years ago the treatment of wastewaters from gold mills was limited to natural degradation in tailings ponds. One exception to this was the very limited application of the acidification-volatilization process which will be described briefly later in this presentation.

Natural degradation remains the most common method for cyanide removal. However, over the past 4 years a number of other chemical processes have been applied for the treatment of gold mill wastewaters. These, as mentioned earlier include alkaline chlorination, Inco's SO_2-air process, Homestake Mining's biodegradation system, Degussa's hydrogen peroxide process and the Con Mine's iron sulphide process. The acidification process continues to be used at one gold mill.

I will now say a few words about each of these processes.

Natural Degradation:

Natural degradation involves the removal of cyanide in gold mill wastewaters by natural means while the wastewaters are detained for prolonged periods in tailings or holding ponds. The degradation of cyanide results from a combination of physical, chemical and biological processes, including: volatilization, photodecomposition, chemical oxidation, microbial oxidation, chemical precipitation, hydrolysis and adsorption on solids. Of these mechanisms volatilization is considered to be the most important. Natural degradation is influenced by a number of variables, including: cyanide species and their concentrations in solution, pH, temperature, bacteria present, sunlight, aeration, and pond conditions (area, depth, turbidity, turbulence, ice cover). Few studies have been done to quantify these processes. During the past 3 years Environment Canada has carried out considerable experimental work in order to better understand and mathematically model the natural degradation process. Mrs. L. Simovic will be describing in her paper details of the studies carried out at Environment Canada's Wastewater Technology Centre (5).

Although cyanide removal by natural means may produce acceptable effluents in some cases, one has only to recall the analyses of tailing pond effluents presented in Table 4 to be convinced that this is generally the exception, not the rule. Admittedly, the tailings ponds from which these effluents were released were primarily intended to separate and retain solids and were not designed to take maximum benefit of the natural degradation process. Considerably better understanding of this process is required before it will be possible, if ever, to employ this method in a general and practical manner to consistently meet regulatory standards.

However, it is worth noting that even in cases where natural degradation cannot produce a final effluent of suitable quality it can still be advantageously employed as a valuable intermediate step for the partial, and perhaps considerable, elimination of cyanide prior to chemical treatment. In fact advantage is being taken of this at some gold mills which do treat tailing pond overflows.

Evaporation

At gold mines in arid regions advantage is taken of evaporation to preclude the discharge of wastewaters. This is common practice at gold mines in the south-western United States, Australia and South Africa. In fact the U.S. EPA's effluent limitation for gold mines in areas of net evaporation is one of zero discharge of process wastewaters.

Chemical Treatment Methods

The inability to produce wastewaters of acceptable quality by natural means has led to the wide interest and growing application of chemical treatment methods for this purpose.

Alkaline Chlorination

Although the alkaline chlorination process has been well known and industrially employed for considerable time, it has been applied to the treatment of gold mill effluents only within the past 4 years. I will first describe the results of full scale performance evaluations carried out during the past 3 years at 4 gold mills in Canada and then present additional information obtained from a fifth gold mine operating in California.

The alkaline chlorination process destroys cyanide (except iron cyanide or more stable cyanide-metal complexes) by oxidation with chlorine under alkaline conditions. Chlorine can be provided in the forms of gaseous chlorine or sodium and calcium hypochlorite. Lime is commonly used for pH control.

The complete oxidation of cyanide to nitrogen and bicarbonate requires 2 stages. During the first stage, cyanide is oxidized and hydrolyzed in two steps to cyanate according to the equations:

$$NaCN + Cl_2 \longrightarrow CNCl + NaCl \qquad (1)$$

$$CNCl + 2NaOH \longrightarrow NaCNO + NaCl + H_2O \qquad (2)$$

The oxidation of cyanide-metal complexes is exemplified by the following reaction for the zincocyanide complex:

$$Na_2Zn(CN)_4 + 10NaOH + 4Cl_2 \longrightarrow 4NaCNO + 8NaCl + Zn(OH)_2 + 4H_2O \qquad (3)$$

The second stage of the process, i.e., the further oxidation of cyanate to nitrogen and bicarbonate, can be represented by the overall reaction:

$$3Cl_2 + 2NaCNO + 6NaOH \longrightarrow 2NaHCO_3 + N_2 + 6NaCl + 2H_2O \qquad (4)$$

Reactions (1) - (3) are carried out at pH 10.5 minimum and reaction (4) at about pH 8.5. Considerably greater reagent additions and longer retention times are required in completing both stages. As a consequence of both higher costs and the relatively low toxicity of cyanate (1/1000 the toxicity of free cyanide) regulatory agencies generally require the process to be carried through only the cyanate stage.

During chlorination oxidizable substances other than cyanide, i.e., thiocyanate, thiosalts and metals in low oxidation states consume additional chlorine. A dramatic increase in chlorine demand results when appreciable amounts of thiocyanate are present in gold mill effluents, as unfortunately is often the case.

The first alkaline chlorination systems in Canadian gold mills were installed about 4 years ago. Since that time as many as 6 companies have employed this method and currently 4 mills are operating such systems. During the period from October, 1981 to March, 1983, Environment Canada with the assistance of a consultant, completed a study of the performances of the alkaline chlorination systems at 3 gold mills (Mosquito Creek, Baker and Carolin) in British Columbia. Environment Canada also evaluated the treatment system at a fourth mine (Giant Yellowknife). Detailed reports on these studies have been published (6,7).

Information pertinent to the alkaline chlorination systems is summarized in Table 5. Barren bleed solution were treated at 3 of the mills and tailings pond decant at the fourth. Gaseous chlorine was used as the oxidant in 3 of the mills and solid calcium hypochlorite at one. Except for Giant Yellowknife the treatment systems are located within the mill buildings. Giant Yellowknife has a separate treatment plant located adjacent to the discharge end of its tailings pond. This plant cost $2,000,000.00 to construct in 1981.

This company operates a 2 stage treatment system for the removal of both cyanide and arsenic. A simplified flowsheet of this plant is shown in Figure 2. Cyanide and metals are removed by chlorine addition in stage 1 and arsenic is precipitated in stage 2 by the addition of ferric sulphate. After flocculation the treated effluent from this plant is discharged to a large polishing pond with 15 days retention time. This pond is effective in greatly improving effluent quality. The plant is operated during the ice free period from May to October.

Typical influent and effluent analyses for the 4 alkaline chlorination systems are presented in Table 6.

TABLE 5 PLANT INFORMATION

Fe	9.4	8.0	2.4	2.8	150	53	<0.1	<0.1	<0.10
Ni							1.2	0.7	
Zn	93	1.4	740	3.9	110	5.8	0.1	0.1	<0.10
% Removal									
CN_T(4)		91.9		99.6		83.0		82.7	98.0
CN_W(5)		98.8		99.9		99.9		85.1	98.7

(1) Cyanide reactor effluent
(2) Polishing pond overflow
(3) Interference during chemical analysis - no analysis
(4) CN_T - Total cyanide by distillation method
(5) CN_W - Weak acid dissociable cyanide by ASTM Method-C

Additional data, 1984 average analyses (mg/l), for the Giant Yellowknife plant are presented below. The Cl_2/CN_T ratio during this period averaged 16.4/1.

	As	CN_T	Cu	Pb	Ni	Zn	NH_3
Plant Influent	13.7	7.8					
Plant Effluent	0.40	0.05					
Polishing Pond Decant	0.38	0.02	0.04	0.02	0.05	0.05	5.5
% Removal	97.2	99.7					

The excellent quality of the tailings pond decant, except for NH_3, is noteworthy.

Wide variations in the compositions of the treated and untreated wastewaters are shown in Table 6. All systems were extremely effective in removing CN_W with % removals ranging from 98.7 to 99.9%. Some plants were less effective in removing CN_T due to the presence of significant levels of iron in solution. This confirms the ineffectiveness of alkaline chlorination for the removal of iron cyanide. The elevated concentrations of thiocyanate (CNS) are significant since on a pound per pound basis the oxidation of CNS requires nearly twice as much chlorine as does CN.

The chlorine consumption at each of these plants is shown in Table 7. The wide variations in chlorine additions are attributed to: the differences in chemical composition of the influents, the process control method employed and the use of manual control of chlorine additions and for lime in some cases.

TABLE 7 CHLORINE CONSUMPTION

Mill	Max. Cl_2 throughput (kg/d)	Estimated Cl_2 Consumption by Titration (kg/m^3)	Actual Chlorine Consumption (kg/m^3)	kg/kg CN_W
Mosquito Creek	136	4.1	4.7	21
Baker	210	7.5	15	8
Carolin	3600	11.3	17	24
Giant Yellowknife	1600	0.13	0.13	18

The estimated chlorine consumptions shown in this Table were based on redox titrations of the influents. In two cases the actual chlorine additions were substantially higher than those estimated by titration. Also shown in Table 7 are the kilograms of chlorine added

per kilogram of CN_W. One must realize that these are rather fictitious ratios in the sense that chlorine reacts with oxidizables in the solutions other than cyanide, notably thiocyanate, thiosalts and metals in low states of oxidation. In fact, in the case of Giant Yellowknife considerable As^{3+} may be oxidized to As^{5+} before removal with ferric sulphate.

The alkaline chlorination process is being used at the 500 tpd Grey Eagle open pit mine near Eureka, California to treat about 400 US gpm tailings pond overflow. As well as receiving mill waste effluents, the tailings pond also receives acidic drainage, containing high iron levels, from an adjacent abandoned underground mine. The treatment plant contains 3 chlorination reactor tanks in series followed by 2 clarifiers in parallel. The clarifier underflows are returned to the tailing pond and the overflows are pumped to a designated land application site. Gaseous chlorine is added to provide a chlorine/total cyanide ratio of about 7.5/1. Retention time in the reactor tanks is 45 minutes at pH 10-11. Table 8 shows typical analyses of water to and from the treatment plant.

TABLE 8 TYPICAL ANALYSES AT GREY EAGLE TREATMENT PLANT (MG/L)

	Tailing Pond Decant	Treated Effluent
CN_T	400	<5
CN_F(1)	250	0.2
Cu	300	0.5
Fe	400	0.3

(1) CN_F is determined using a cyanide specific electrode.

The iron chemistry associated with this plant remains unexplained. Considerable amounts of iron enter the tailings pond in the acidic abandoned mine drainage but this iron does not precipitate at the pond water pH of 8-9. Fortuitously, the iron apparently does not react with the free cyanide in the mill effluent to form stable iron cyanide complexes. This is confirmed by almost complete iron removal during treatment even though it is well known that alkaline chlorination is ineffective in removing iron cyanide.

The alkaline chlorination process is used for treating a slurry at Duval's Battle Mountain, Nevada mining operation. Also, until recently, it was used to treat a slurry at a gold mine in northern Ontario. However, since the chlorine requirements were extremely high this mine has discontinued this practice. Currently chlorination tests on tailings pond decant are being run at pilot plant scale in order to take advantage of some cyanide removal by natural degradation in the tailings pond prior to chlorination.

INCO SO_2- Air Process

In 1982 Inco Metals Company announced the development of a novel method for the destruction of cyanide in gold mill waste streams. The process involves the selective oxidation to cyanate of both free and complexed cyanide species (with the exception of iron cyanide) using a mixture of SO_2 and air at controlled pH (about 9-10) in the presence of copper as a catalyst. Except for iron, metals are precipitated from solution as hydroxides. The process also removes iron cyanide, not by oxidation, but by precipitation as an insoluble copper or zinc ferrocyanide.

The destruction of cyanide by oxidation may be represented by the equation:

$$CN^- + O_2 + SO_2 + H_2O \longrightarrow CNO^- + H_2SO_4$$

This process should not be confused with the older method of acidification-volatilization in which the pH of barren bleed solution is essentially lowered to 2-3 in order to rapidly dissociate metal-cyanide complexes and expel cyanide as hydrogen cyanide gas.

In Canada, the SO_2-air process is receiving wide attention for the treatment of gold mill effluents. Three companies are currently using the process and two others will be doing so next spring. Three companies, previously using alkaline chlorination, have converted to the SO_2-air method due to iron removal problems or high reagent costs. Two of the mills are no longer using the process since one mill has shut down and the second has discontinued gold recovery by cyanidation. Of the three mills currently applying this process, one is treating barren bleed solution and two are treating tailings slurries. The next two users will be treating tailings pond decant.

The SO_2 required for the process may be supplied in a variety of forms, i.e., as gaseous sulphur dioxide, as a soluble sulphite or meta-bisulphite, or as roaster gases containing SO_2. Currently only sodium sulphite and sodium metabisulphite are being used.

I will not describe the process or its application in more detail since Dr. B. Conard of Inco will be doing so later.

However, I would like to add that from what we have learned to date from full scale application, the SO_2-air process appears to offer an effective means to treat gold mill effluents, in either aqueous or slurry forms, to produce effluents containing concentrations much less than 1 ppm for CN_T and for each of the metals commonly found in gold mill effluents, i.e., copper, iron, nickel and zinc.

Due to its recent application further assessment of the process is required, particularly in regard to the toxicity of the treated effluents and the stabilities of the metal-ferrocyanide precipitates produced. Initial investigations by Inco indicate these precipitates to be quite stable ove wide range of pH.

One advantage of the process, from a reagent conservation point of view, i.e., the slow oxidation and removal of thiocyanate, could prove to be a disadvantage in situations in which the removal of thiocyanate may be required. However, thiocyanate may be removed by changing process conditions.

Several reports describing the SO_2-air process have been published (8,9,10,11,12).

Homestake Mining's Biological Process

Until only recently the removal of cyanide from gold mill wastewaters by bacteria has been neither practiced nor received a great deal of attention. The reasons for this in Canada are twofold. First, in the case of barren bleed, these solutions contain both cyanide and metals at sufficiently elevated levels to render them hostile to the support of bacterial activity. In the case of tailings pond water, which contains both cyanide and metals at substantially reduced concentrations due to natural degradation and dilution, biological treatment has been ruled out, at least in Canada, due to low water temperatures during frigid winter conditions.

However, at one gold mine, Homestake Mining Company at Lead, South Dakota, the biological treatment of mill wastewaters has become a reality. Over the past 2-3 years Homestake has developed a biological process to treat their combined mine and tailings impoundment wastewaters. An essential requirement for the successful operation of this process is the ability to blend mine water (70-85°F) with tailings impoundment water (34-70°F) to maintain a year round combined wastewater temperature sufficiently warm (50-65°F) to sustain effective biological process rates. A 3600 US gpm treatment plant was put into operation this past August at a capital cost of approximately $10,000,000.00.

The development of the biodegradation process, which began in 1981, and the design of the full scale treatment facility was described in a 1983 paper authored by Dr. T.I. Mudder and J.L. Whitlock of Homestake Mining (13).

The principal contaminants of concern in Homestake's wastewaters are cyanide, thiocyanate, copper and ammonia. The compositions of the two wastewaters to be treated in the plant are indicated in Table 9.

TABLE 9 COMPOSITION OF WASTEWATERS (MG/L)

PARAMETER	MINE WATER	TAILINGS IMPOUNDMENT WATER
Thiocyanate	1.0-16.0	110.0-240.0
Total Cyanide	0.10-0.50	7.00-30.0
* Method-C Cyanide	0.02-0.10	4.00-20.0
Iron	0.10-10.0	1.50-6.0
Copper	0.07-1.6	1.40-6.0
Nickel	0.01-0.04	0.20-0.40
Zinc	0.01-0.10	0.01-1.5
Ammonia-N	5.0-6.0	less than 1.0
Phosphorus-P	trace	trace
pH	5.0-6.5	7.0-9.5
Temperature (°F)	70-85	34-70

* ASTM Method-C for the analysis of weak acid dissociable cyanide doesn't included cyanide present as iron cyanide.

A simplified flowsheet of the process is shown in Figure 3.

Homestake's biological process is carried out in two stages. The first consists of the bacterial oxidation of cyanide and thiocyanate to carbon dioxide, sulphate and ammonia concurrent with the adsorption of metals by the bacteria. The second stage involves the bacterial nitrification of ammonia to nitrate. Different strains of bacteria are involved in the various stages of the process. Homestake Mining has received two patents for the use and the specific bacteria responsible for the oxidation of cyanide and thiocyanate. Metals associated with cyanide and thiocyanate are removed, once free from cyanide, by adsorption by the bacteria (biofilm) which are attached to slowly rotating vertical disks in tanks (rotating biological contactors). As the biofilm continuously sloughs off the disks the bacteria-metal sludge is removed from the effluent by clarification and dual-media sand filtration and returned to the tailings pond.

Forty-eight rotating biological contactors, with partially submerged disks 12 feet in diameter, are used to contact the bacteria with the wastewater and air. The first 24 contactors are used in the cyanide and thiocyanate removal stage. The contactors are not housed but all are well insulated. The only reagents added are soda ash as an inorganic carbon source to aid nitrification, and phosphorus as a trace nutrient. Following the biological contactors ferric chloride and/or a polymer are added prior to clarification and sand filtration.

The plant is reported to be operating satisfactorily to produce effluents of the quality predicted from the pilot plant tests. The compositions of the influents and effluents typical of both the operation of the pilot plant and the full scale facility are given in Table 10.

TABLE 10 WASTEWATER COMPOSITIONS MG/L)

	PILOT PLANT		FULL SCALE PLANT	
	INFLUENT	EFFLUENT	INFLUENT	EFFLUENT
Total Cyanide	6.5	0.35	2.0	0.30
Method-C Cyanide	4.1	0.05		0.02
Thiocyanate	60.0	1.0	50.0	< 0.10
Ammonia	6.0	0.50		0.10
Copper	1.0	0.04	1.0	0.05
Suspended solids				<10.0

The Homestake experience has rekindled considerable interest in the biodegradation of gold mill effluents.

Degussa's Hydrogen Peroxide Process

Although the destruction of cyanide by oxidation with H_2O_2 is well known, the process has only recently been applied to the continuous full scale treatment of a gold mill waste stream. The previous reluctance to apply this process appears to result from its economic unattractiveness.

The destruction of cyanide by H_2O_2 is shown by the reaction:

$$CN^- + H_2O_2 \longrightarrow CNO^- + H_2O$$

In May 1984 OK TEDI Mining Limited in Papua New Guinea brought on stream its 22,500 mt/day gold mill, a giant operation by gold mill standards. Cyanidation and the CIP process are employed for gold recovery. Hydrogen peroxide solution is added directly to the CIP tailings slurry and reacted in an agitated tank to oxidize cyanide to cyanate before discharge. The novelty of the Degussa process is, of course, not the use of hydrogen peroxide for detoxifying gold mill effluents but rather the closely controlled, automated and efficient manner in which the H_2O_2 is utilized.

Without wishing to detract further from Dr. Griffith's later presentation (14) I will only add that the Degussa process is being used effectively at OK TEDI to meet extremely stringent government requirements. Without doubt the continued performance of this process for cyanide destruction will be followed with great interest.

Con Mine's Iron Sulphide Process

Cominco Limited operate a conventional 700 tpd gold mining and milling operation on the shore of Great Slave Lake. Following

the milling process, waste barren bleed solution is treated by the addition of ferrous sulphide to remove both free and complexed cyanides. Finely divided insoluble ferrous sulphide particles are prepared in the mill by reacting ferrous sulphate with sodium sulphide, prior to adding the ferrous sulphide slurry to the waste barren bleed. The removal of cyanide results from the adsorption of cyanide on the ferrous sulphide particles. The reaction which is strongly pH dependent is carried out at pH 7.5 at a flow of about 20 igpm and a retention time of about 15 minutes. The ferrous sulphide to cyanide ratio is maintained near 3 to 1.

The treated effluent from the process is discharged to the mill tailings launder. In the tailings launder ferrous sulphide continues to adsorb cyanide from the water entering with the filtered leach tailings. Ferrous sulphate is also added to the launder to remove arsenic which dissolves from the ore. The cyanide removal step is not intended to produce an effluent of suitable quality to meet the company's effluent discharge limits but relies on further removal of cyanide by natural degradation in the tailings ponds.

Typical analyses of influent to the treatment process and effluent from the tailings pond are presented in Table 11.

TABLE 11 WASTEWATER ANALYSES (MG/L)

	Influent to FeS Process	Tailings Pond Decant	License Conditions
As		0.3	0.50
CN_T	750	0.7	1.5
CN_W		0.35	0.40
Fe	140		
Cu	50	0.3	0.30
Zn	155	0.04	0.30

Acidification

The acidification process is being used at the Emperor Gold Mine in Fiji to remove residual cyanide from cyanided and washed roaster calcine subsequent to a flotation step to recover sulphides. To remove the cyanide the calcine slurry is acidified from pH 9 to 2.5 by being sprayed into a tower counter-currently to SO_2-containing roaster gases. Cyanide is eliminated as HCN gas directly to atmosphere.

The well known Mills-Crowe process of acidification-volatilization-regeneration involves acidifying waste cyanide bearing solutions to pH 2-3 with H_2SO_4 or SO_2, volatilizing the resulting HCN by air flushing and recovering the HCN by absorption in an alkaline solution, i.e., NaOH on $Ca(OH)_2$. The recovered cyanide is the recycled to the cyanidation circuit for reuse. This process is still

in operation at a silver mine in Mexico operated by Compania Beneficiadora de Pachuca. Elemental sulphur is burned to produce SO_2 for acidification of the waste barren solution.

The Mills-Crowe process was used for cyanide recovery by Hudson Bay Mining and Smelting Company at Flin Flon from 1935 to 1978 while the company was cyaniding a base metal tailing for the recovery of gold. Waste barren solution was acidified with a H_2SO_4 solution from their zinc recovery plant. Air was used in towers to sweep HCN from the acidified barren solution and the HCN was absorbed in $Ca(OH)_2$ for reuse in the cyanidation circuit. Ninety-one percent of the "regenerable" cyanide was recovered in this manner. "Regenerable" cyanide was the amount of cyanide which could be released from the waste barren solution in a laboratory acidification test.

The acidification process has been employed principally for cyanide recovery, not for environmental protection and therefore, it is not known what quality of wastewater could be produced by this method if environmental protection was the main goal.

Conclusions

Natural degradation continues to be the most common method employed for the treatment of gold mill wastewaters. However, due to its limitations in producing final effluents of desired quality there has been a growing interest in, and application of, chemical treatment processes. In only a few years the gold mining industry has made considerable progress in demonstrating at full scale a number of effective chemical treatment systems. The two which are used most widely are the alkaline chlorination and the Inco SO_2-air processes.

Some of the processes in commercial operation are capable of removing up to 99.9% weak acid dissociable cyanide and close to that for total cyanide, especially in the absence of iron cyanide.

Since these chemical methods have been in use for only a limited period of time they require further performance evaluation with particular regard to the quality of the treated effluents. A serious shortcoming in the examination of most of the processes has been the lack of sufficient toxicity testing of the resulting effluents. These effluents may contain many substances, e.g., cyanide, metals, chlorine, thiocyanate, cyanate and ammonia which could be present in toxic concentrations. Effluent toxicity must be critically examined to determine that if in attempting to solve the cyanide problem, a new one isn't being created, albeit less severe than the original problem.

However, there are now several commercially demonstrated methods for cyanide removal. The final selection of a method for a specific mill will require careful consideration of the nature of the specific effluents to be treated, the regulatory limits imposed upon the mining company and the alternative treatment costs.

FIGURE 3 BIOLOGICAL TREATMENT PROCESS AT HOMESTAKE MINING COMPANY

OVERVIEW OF CYANIDE TREATMENT COSTS

The direct comparison of cyanide treatment costs from one location to another would be misleading. The cost of reagents varies greatly from site to site. Also, the degree of treatment needed varies from nil to aggressive treatment, depending on performance demanded to meet effluent regulations, whether the site is zero discharge or not, whether natural degradation does all or most of the work requiring minimal additional treatment, whether iron cyanides can be tolerated in effluents, etc., etc.

Some distinction must also be made as to whether the cost parameters are based on real plant experience or on calculated parameter estimates by equipment, chemical, or process vendors.

A few fragmentary items of information on cost parameters gathered in the course of this study are listed below:

ALKALINE CHLORINATION

1. Giant Yellowknife Mines, Northwest Territory, Canada

C/2 Consumption to Achieve 1 ppm CN_T	18 lbs. Cl_2/lb. CN_T 0.3 lbs. Cl_2/ton Ore Solids 14.7 lbs. Cl_2/ton Calcine
Capital Cost (1981)	C$1.9 Million
Operating Cost (1983)	C$780,000/Year
Cost per 1,000 1 Gallons (1983)	C$2.45/1,000 Gal.
Cost per Ton Ore Treated (1983)	C$2.40/t

Performance (mg/l):

	Infl.	Eff.	Polishing Pond Overflow
CN_T	7.5	1.3	0.15
CN_W	7.1	1.2	0.09
CN_S	6.3	1.0	-
Cu	6.7	0.09	0.03
Zn	0.1	0.1	LT 0.10

2. Superior Minerals, Stibnite, Idaho (3,000 tpd HL)

Calcium hypochlorite generated on site.
1.25 lb. $Ca(OH)_2$ added per 1 lb. Cl_2.
4,000 lb. Cl_2/day consumed @ $360/t delivered = $720/day.
12st Cl_2 consumed over 6 days for 30,000t heap = 0.8 lb. Cl_2/ton ore ($0.14/ton ore).
Application rate: 240 U.S. gpm.
Lime cost (pebble lime used) (estimated) = $170/ton $Ca(OH)_2$.
Lime use = 1.25 lbs. $Ca(OH)_2$ per lb. Cl_2 = 1 lb./ton ore ($0.09/ton ore.
Cost of reagents for Superior Mines heap neutralization:

Chlorine - 0.8 lb./ton @ $0.18 =	$0.14/ton ore
Lime - 1.0 lb./ton @ $0.09 =	$0.09/ton ore
	$0.23/ton ore

Comparative cost of $Ca(OCl)_2$ - 60% effective; $Ca(OCl)_2$ - 1.33 lb. @ $1.30 = $1.60/ton ore.

3. Northern California Gold Mine Comparison

Based on Lab Tests:

Alkaline Chlorination	$3-6/lb. CN Neutralized
INCO SO_2-Air	$2-3/lb. CN Neutralized
H_2O_2	$13-14/lb. CN Neutralized
Biological	$1.00/lb. CN Neutralized

Actual Costs for Alkaline Chlorination of Tailings Decant Solution with Relatively High Cu Levels:

$6.34/1,000 U.S. Gallons

Reagent Consumption:

Cl_2 11.1 lb./1,000 U.S. Gal.
NaOH 37.2 lb./1,000 U.S. Gal.

Performance:

Influent:	75 ppm CN_T
Treated:	0.10-0.20 ppm CN_F
	5 ppm Max. CN_T

Operating Costs for SO_2-Air Cyanide Removal

DEVUYST, et al. (1984) gave the following theoretical reagent requirements for a gold mill effluent (barren + tails) containing, for example, in mg/l: 250 CN_T, 250 SCN^-, and 100 $S_2O_3^=$:

Species	Reagent g/g CN_T $Na_2S_2O_5$	Lime
CN^-	3.73	1.42
SCN^-	0.67	0.38
S_2O_3	0.17	1.67
	4.57	3.47

Reagents for SCN^- are based on average oxidation of 10% of SCN^- and complete oxidation of S_2O_3 to S_4O_6. Using empirical reagent efficiencies of 90% for $Na_2S_2O_5$ (10% oxidized by air) and 75% for lime (25% unreacted), the reagent requirements for the above effluent are 5.08g $Na_2S_2O_5$ and 2.23 lime per gram CN_T oxidized.

Based on FOB Vancouver prices reported by DEVUYST, et al. (1984), the cost of the process would be as follows:

Reagent	Price ($/mt)
$Na_2S_2O_5$	550
Lime	180
$CuSO_4.5H_2O$	1,320

Assuming the addition of 25 mg/l Cu^{++}, the cost of treating the hypothetical effluent is C$0.95/m³.

For a typical gold mill treating 1,000 mt of ore per day at 2 lbs. NaCN/ton, the cost per metric ton milled is $1.90, or a yearly cost of $693,000 for reagents.

DEVUYST, et al. (1984) find that at a chlorine cost of C$725/mt, the reagent costs for the same waste treated by alkaline chlorination would be C$2.72/m³ or C$5.44/mt for a yearly reagent cost of C$1,980,000.

	Cost of Reagents per m³ Pulp*	Cost of Reagents per t Ore	Annual Costs for 1,000 tpd
SO_2-Air	C$0.95	C$1.00	C$693,000
Alkaline Chlorination	C$2.72	C$5.44	C$1,980,000

* (250 mg/l CN_T, 250 mg/l SCN^-, 100 mg/l $S_2O_3^=$)

BIOLOGICAL PROCESS - HOMESTAKE MINING CO., LEAD, SOUTH DAKOTA

Capacity: 21,000 m^3/d (3,800 U.S. gpm)

Process: 48 Rotating Biological Contactors

FIGURE 2

ALKALINE CHLORINATION PLANT

FLOW SHEET

CONTROL OF CYANIDE CHLORINATION BY ORP

The reason that total cyanide is not removed by chlorination is that iron cyanide complexes are not decomposed. For flotation tailings where the iron cyanide remains in a solid-liquid pulp which is opaque to sunlight, this is believed unlikely to represent a problem. Where effluents are decanted to shallow exposed streams, photodecomposition of ferrocyanides to cyanide has been reported among others by Environment Canada tests.

CHEMISTRY OF ALKALINE CHLORINATION

The chemical reactions which occur during alkaline chlorination were described by INGLES & SCOTT (1981) and were reproduced on page 1352 of the RANDOL PHASE II report "Innovations in Gold & Silver Recovery," also in HUIATT et al. (1982) and are copied again here for convenience in Table 12.

DESCRIPTION OF ALKALINE CHLORINATION PROCESS

The alkaline chlorination plant is quite simple. It consists of a tank, sized appropriately for the retention time required, equipped with a mixer and baffles to ensure thorough mixing and contact.

The tank is equipped with feed lines and pH as well as ORP probes. A second tank with mixer and baffles is usually placed in series with the main tank and should preferably be equipped with pH and ORP probes. The second tank ensures an adequate retention time for all reactions to be completed and is a safeguard in case the effluent did not get properly contacted in the first tank. (Short circuiting in a one tank mixing system is inevitable.)

Equipment must be corrosion-resistant. Tanks are preferably fiberglass with mixers of coated steel.

Liquid chlorine is supplied in bulk tanks or in one-ton cylinders and is injected into the line by a water jet. Feed rate is measured by flow meters and most desirably controlled by the ORP as discussed below.

For high chlorine demands, say 500 lbs/day or more and for systems in cold climates it may be necessary to use an evaporator which vaporizes liquid chlorine using electric heaters prior to water injection. The gaseous Cl_2 system employing cylinders is arranged in such a way that in the event the pressure drops in the cylinder in use, the system automatically switches over to the next tank. Such systems are employed at Giant Yellowknife and at Noranda Grey Eagle Mines Ltd.

If "solid forms of chlorine" are to be used, this is invariably supplied as calcium hypochlorite $Ca(OCl)_2$ and is added by an adjustable speed dry feeder. Such systems are installed at remote sites which can only be reached by air.

At Battle Mountain Operation of Duval Corp. and at Superior Mineral's Stibnite, ID plant liquid chlorine is first evaporated and then mixed with NaOH or $Ca(OH)_2$ solution to make a solution of NaOCl or $Ca(OCl)_2$ which is injected into the system.

At the Climax Mine of AMAX Inc. it is reported that Chlorine dioxide is used which is generated on site in equipment provided by Olin Corporation but this has not yet been confirmed.

Various ways are used to deal with the precipitates that form depending on the fate of the product solutions or pulps.

1) Climax Mine removes metal precipitates using Lectroclear flotation before alkaline chlorination and follows alkaline chlorination with downflow gravity filtration.

2) Noranda Grey Eagle Mines employs a clarifier to settle flocculated precipitates and then filters the effluent.

3) Superior Minerals at Stibnite, Idaho, uses the hypochlorite solutions to rinse heaps after leaching before moving the heap materials to the tailings dump.

4) Giant Yellowknife follows alkaline chlorination with arsenate precipitation and then settles the precipitates in a settling pond.

5) At Battle Mountain and at Detour Lake the oxidation and precipitation products are contained in tailings pulp which is pumped to the tailings pond.

Although relatively simple in principle it has been found that chlorination systems have been high maintenance items and more operator time intensive than anticipated. Potential users are recommended to investigate the pros and cons experienced in existing systems elsewhere.

ALKALINE CHLORINATION PROCESS CONTROL

The process is controlled by pH and by oxidation-reduction potential ORP.

Alkaline chlorination proceeds in two stages. The first stage to CNO^- proceeds rapidly at pH 10-11, the second stage is slower but goes fastest at pH 8.5 (below 9) to $CO_3^=$, NaCl and N_2. The second stage is not so sharply observed in ORP charge with breakpoint

occurring at 400 mV. Some operators do not recommend the use of ORP control in the presence of NH_3.

Most effluent treatment operations take the process only to completion of the first stage in the plant.

pH is controlled by adjusting the lime solution addition rate to maintain pH 11.

Chlorine is added to maintain redox potential at which it has been determined that all CN_T has been destroyed. Usually this is around -600 mV.

According to JACKSON (date not known) just sufficient chlorine must be added to reach "A" as recorded by the ORP signal from the probe in the first reaction tank and to maintain that level.

Point "A" must be determined experimentally using the actual solution to be treated and verified in the actual operation. This is done with chlorine (hypochlorite is more convenient in the laboratory) to obtain a curve similar to that shown below. ORP is affected to a degree by pH and this must be taken into account when determining point "A". Also, copper, if present in solution, is said to poison platinum ORP electrodes, and some process engineers prefer gold-calumel or silver amalgam electrodes. Reference:

FRED STEVENS
Lancy International
Zelienople, PA

Jim Scott of Environment Canada, Ottawa, referred to a new continuous Cl_2-monitor being developed for plating waste treatment plants which would be useful for controlling alkaline chlorination.

When chlorine is used as a reagent the signal from the ORP probe in the first tank should be used to control the chlorine feed automatically - maintaining level "A" even though effluent flow rates and dissolved cyanide levels may vary. With dry hypochlorite, manual control of the feed rate is usual although presumably the ORP signal could be hooked up to the feeder speed.

A simple field check test for the presence of free chlorine is the instaneous appearance of a blue or purplish blue color when a sample of treated effluent is spotted on a starch-iodide test paper.

A potentially more practical approach for controlling CNaddition for solutions with appreciable levels of copper is to analyze copper which is easy. One northern California operation found that when the copper had been reduced from 300 mg/l to below their

criterion of 0.2 mg/l or so, the free cyanide would always be below 0.2 mg/l in their treated effluent.

REAGENT USAGE

In accordance with the summary equation:

$$2NaCN + 2Cl_2 + 2Ca(OH)_2 = 2\ NaCl + CaCl_2 + Ca(CNO)_2 + H_2O$$

The amount of lime, expressed as CaO needed is 2.2 lbs per lb CN. In practice somewhat more is needed to maintain pH 11 depending on how much other chlorine consumers are present which also consume hydroxyl ions when they react.

The theoretical amount of Cl_2 needed is 2.73 lb Cl_2/lb CN. In practice chlorine demand is also higher than this depending on the concentration of other chlorine consumers - e.g.:

Thiocyanate oxidation
Copper (oxidation from cuprous to cupric)
Ammonia (15 - 20 lb Cl_2 per lb NH_3)
Thiosulfate and thiosalt oxidation

ADVANTAGES AND DISADVANTAGES OF ALKALINE CHLORINATION
(Expanded from HUIATT, et al. (1982)

Advantages:

1) Very widely used method, expertise is available
2) Most feed streams are already alkaline
3) Reactions are complete and fairly rapid
4) Chlorine is readily available in several usable forms
5) Toxic metals are removed
6) Readily adaptable to either continuous or batch operation
7) Capital outlay is relatively low
8) Good fail-safe control
9) Easily controlled to first stage of oxidation if disposal of CNO^- is permitted
10) Can destroy NH_3 if desired
11) Synergistic oxidation of As to As^{+5} is possible ahead of precipitation
12) Chlorination of tailings should result in improved gold loading on carbon columns used to treat decant solution due firstly to incremental Au leach and secondly to remove of base metal cyanides before carbon adsorption.

DISADVANTAGES OF ALKALINE CHLORINATION

1) Reagent costs are high especially if complete oxidation is required. Thiocyanate, thio-salts and ammonia are additional heavy consumers of chlorine.

   1 g CNS^- requires 4.9 g Cl_2

   1 g NH_4 requires 15 - 20 g Cl_2 to breakpoint

2) Requires careful control of pH to prevent formation of cyanogen chloride which is very toxic.
3) Chlorine gas is toxic in the work environment.
4) In cold climates where cyanide destruction is most likely to be required, chlorination plant is installed indoors resulting in an unpleasant work environment. Giant Yellowknife has found a way around this.
5) For locations reachable by air transportation only, solid forms of chlorine are required. These are costly per unit Cl_2 and when used in some solutions result in buildup of metal precipitates in the reactor.
6) Chlorination processes are tricky to control. Complaints of larger than expected volumes of precipitate and scaling problems.
7) For complete removal of CNS a two stage reaction is required. Stage I at pH 11.5 and Stage II below pH 9. This requires complicated plant and process control.
8) Cyanide is not recovered.
9) Hexaferrocyanates are not usually decomposed.
10) Metal values are not recovered.
11) Chloride content of effluent is increased in direct proportion to the chlorine added.
12) Possibility of forming toxic chlorine derivatives e.g., chlorinated organic compounds that require further treatment.
13) Residual excess chlorine can be toxic to aquatic species. It can readily be removed by $S_2O_3^=$ or H_2O_2 addition or activated charcoal columns, but an extra step is needed.
14) Chlorine is very reactive and if tailings pulps are to be chlorinated consumption of Cl_2 may be excessive due to reactions with solids in the pulp.
15) According to vendors of a competing process, cyanide destruction in tailings pulps using Cl_2 has great difficulty achieving most regulatory permit limits.
16) Chlorine is very reactive. Steel components require frequent maintenance and in some cases replacement after 4 - 5 years.

APPLICABILITY OF ALKALINE CHLORINATION

MUDDER & WHITLOCK (1984) report alkaline chlorination as being particularly viable for effluents with low CNS^- and Fe where the chlorine consumption will be lower and a single stage reaction is all that will be required.

Because of the very high consumption of Cl_2 by NH_3 (15 - 20 g Cl_2 per g NH_3) chlorination will be very expensive for solutions containing appreciable levels of NH_3.

Because of reactions between solids in tailings pulp with highly reactive chlorine, use of chlorine for treatment of some pulps may be inapplicable for cost reasons.

Three alkaline chlorination plants were replaced by SO_2-Air treatment in Canada. The reasons that alkaline chlorination was found to be inappropriate at these installations were:

SCOTTIE GOLD, STEWART, B.C.

The cyanided ore contains pyrrhotite which produces high amounts of ferrocyanide in the tailings which decant to a river flowing from British Columbia into a salmon river in Alaska. Cl_2 treatment failed to remove ferrocyanides.

The use of solid hypochlorite in the underground mill at Scottie resulted in operation problems in which the system became congested with solid precipitates. There were safety problems in adding enough hypochlorite into the system.

SO_2-Air treatment resulted in much more comfortable operating conditions.

DUPONT EXPLORATION, BAKER MINE, NORTH CENTRAL B.C.

The alkaline chlorination process was replaced by SO_2-Air for economic reasons when the tailings as well as barrens were to be treated towards the end of the life of the silver mine as ore reserves were depleted.

Alkaline chlorination worked well for the small barren bleed stream of 3 - 4 gpm containing up to 3 g CN^-/l.

This operation experienced no environmental problems and the conversion to SO_2-Air was purely economical because of the lower cost of sodium sulfite requirements than hypochlorite to treat the ore. All supplies to this mine had to be air freighted to the site.

CAROLIN MINES, LADNER CREEK MILL, HOPE, B.C.

After being temporarily shut down on account of effluent and tailings excursions, and being accused by the Provincial and Federal Government of causing fishkills, Carolin Mines had to consider improving their cyanide destruction system.

Even with a second alkaline chlorination treatment facility Carolin's release of tailings decant to the stream was limited because of its ferrocyanide content which was not reduced by alkaline chlorination. As a result of an inadequate bleed from the pond both [Fe] and [CN_T] were building up in the solution resulting in further limitations in release to the stream. A vicious circle was in effect with the potential end result of a third spill when the Provincial and State Government stepped in threatening to close the plant down unless the CN_T was reduced.

Carolin Mines is located on the headwaters of the Fraser River which supports a commercially valuable salmon fishery in southern British Columbia.

After converting the existing chlorination system to SO_2-Air both iron and CN_T levels were reduced. At that time soluble iron levels in the ore increased dramatically and the existing retrofitted reactor was inadequate. An alternative larger system was recommended.

The decision was then made to stop cyanidation and rather to sell a flotation concentrate from the plant thereby eliminating the need for cyanide destruction.

Several operating chlorination plants are discussed briefly below.

GIANT YELLOWKNIFE MINES, YELLOWKNIFE, NWT

Giant Yellowknife is located in an extreme northern climate and experiences a deep freeze for six months of the year. The tailings decant is treated to remove both cyanide and arsenic.

By virtue of the fact that their tailings dam is large enough to accommodate solution that accumulates through the whole winter it is possible to operate an effluent treatment plant for only the summer season. It is sized to treat one year's effluent flow during the six month operating season.

Alkaline chlorination installed in this way avoids the need for indoor reactors. Furthermore in the cyanide decomposition process arsenic is oxidized which is an important first step in Giant's subsequent arsenic removal step with ferric sulfate. Although Giant uses cyanide to leach calcines and is therefore likely to introduce

ferrocyanide into their commingled tailings which will not be removed by alkaline chlorination, this must make up a relatively small part of the overall tailings flow considering the results achieved. Alternatively, in the arsenic removal step using ferric sulfate addition possible ferrocyanide is removed by precipitation of Prussian blue.

Giant's alkaline chlorination plant is said to be one of the very best in concept and is appropriate to their needs. It is discussed in detail in a separate trip report as well as by several authors including PRICE (1981).

Giant's chlorine consumption works out to 13.5 lbs Cl_2 per lb CN_T to achieve levels below 1.0 ppm. This compares with a target Cl/CN_T ratio of 8:1 based on bench scale work and 9:1 on pilot testwork. Theoretical consumption in the absence of other chlorine consumers is 2.7 lbs Cl_2 per lb CN.

Typical Analyses of Giant Yellowknife Effluents (mg/l)

	Flow	pH	As	CN_T	TSS	Fe	Cu	Zn	Ni
Tailings Pond decant before treatment	5000 m^3/d	8.8	12.1	8.6	-	-	6.87	0.10	1.23
Treated Decant Solution	5000 m^3/d	7.7	0.14	0.20	1.20	-	0.08	0.05	0.11

Chlorine and lime consumption make up the major cost of operating this plant. Due to its remote location shipping costs are very high which exaggerates the cost of reagents.

Data for 1983 work out as follows:

Volume of Water Treated:	1,207,000 m^3/yr, 319 mm igpa
Chlorine Consumption:	191 tons
Lime Consumption:	573 tons
Tons Ore Treated:	325,000 tons
Tons Calcine Cyanided:	28,600 tons
Chlorine Consumption=	0.34 lbs Cl_2/ton ore
	14.7 lbs Cl_2 /ton calcine cyanided
	18 lbs Cl_2/lb CN_T
Capital Costs were	C$1,900,000 (1981)
Operating Costs	C$ 780,520 (1983)

Costs per 1000 gallons =	C$2.45/1000 I gallons(1983)
Cost per ton ore treated =	C$2.40/ton ore (1983)

WESTMIN RESOURCES LTD., MYRA FALLS OPERATION

The following account of the installation of an alkaline chlorination plant to treat 200,000 Igpd (757 m^3/d) water containing 4.7 ppm CN_T and 2.85 ppm Cu is of interest.

Firstly, it illustrates some of the operating and maintenance-replacement problems that were encountered. Secondly, it illustrates just how much excess Cl_2 may sometimes be required.

200,000 Igpd solution	= 747 m^3/d	
@ 4.87 ppm CN_T	= 3.63 Kg CN_T^-/d.	= 8.0 lb/d CN
This required 2000 lbs Cl_2	= 250 lb Cl_2/lb CN	

True the excess Cl_2 was carried over with the treated solution to the tailings line where any CN^- in the pulp would also be oxidized by the excess Cl_2, but it appears likely that instead of discharging 8.0 lbs CN^-/day plus some copper, Western Mines may now be adding Cl_2 to the water.

Pollution Control At Western Mines' Myra Falls Operations

A. G. Eccles, Mill Superintendent,
Western Mines Limited,
Campbell River, B.C.

Abstract

Western Mines' milling circuit produces three concentrates (copper, lead and zinc), with the tailings being disposed of at the bottom of Buttle Lake. In view of the mine's location and the method of tailing disposal, a comprehensive pollution control program has been in effect since start-up.

Changes in the ore over the past few years have required the use of increasing quantities of sodium cyanide in order to effect a good copper-lead separation. This led to the use of alkaline chlorination for destruction of residual cyanide and precipitation of dissolved copper contained in the tailing effluent. The development of Western Mines' alkaline chlorination plant is discussed in detail, including initial test work and the evolution of procedures leading to the present operation. The current monitoring program is also reviewed.

Introduction

THE WESTERN MINES LIMITED copper-lead-zinc operations are located in Strathcona Provincial Park, near the geographic center of Vancouver Island. This park includes Buttle Lake, which feeds the Campbell River water system. The latter is the source of domestic water for the town of Campbell River, approximately 58 miles from the mine site.

Operation of the concentrator commenced in December 1966, at which time the tailings were discharged into a small pond near the plant. On May 8, 1967, Permit No. 185 was granted to the company, allowing discharge of the tailings, through a submerged outfall, to the bottom of Buttle Lake.

The concept of operating a mine within a park, and the discharge of tailings into Buttle Lake, generated considerable controversy. However, this has all but been eliminated over the years by the proven effectiveness of Western Mines pollution control program. In 1973, this program was further upgraded by the introduction of alkaline chlorination. Effluent treatment by this method became necessary as a result of process modifications, and has been effective in maintaining the effluent characteristics of the tailings within the ever-increasing pollution control requirements imposed on the industry.

A. G. Eccles was born in Rossland, British Columbia, and received his early schooling in Victoria. He graduated from the University of British Columbia in 1962 with a B.A.Sc. in metallurgical engineering. Following graduation, he was employed in various industries, including steel rolling, lead and zinc smelting, light manufacturing and mineral processing. He joined Western Mines Limited in 1972, where he holds the position of Mill Superintendent.

Mr. Eccles is a member of the C.I.M., the A.S.M. and the British Columbia Association of Professional Engineers.

Plant Operation and Tailing Disposal

COMPLEXITY OF THE ORE

Western Mines is currently mining and milling some of the most complex polymetallic ores in B.C. Compared to most operations containing one major metal, and perhaps a by-product, Western Mines' ores contain recoverable quantities of copper, lead, zinc, gold, silver, and cadmium. In order for the operation to be viable, these metals must be recovered as completely as possible in the form of marketable concentrates.

Separation of the three base-metal sulphides is difficult due to close interlocking, and levels of impurities in the concentrates are high. These impurities are in some cases subject to penalties, and if above specified levels could be grounds for rejection. Table 1 illustrates typical mill feed and concentrate grades.

The three-way selective flotation of these metals presents one of the most complex milling problems, and requires close control of grind, pulp density, pH and reagents in order to achieve the best metallurgical results. These, in turn, must be balanced against the stringent limitations on quality of the tailing discharge.

PRESENT MILLING PRACTICE

The milling circuit consists of conventional crushing and grinding followed by differential flotation to produce separate copper, lead and zinc concentrates. A simplified flowsheet showing the milling and tailing disposal circuits is given in Figure 1.

The first flotation stage produces a copper-lead rougher concentrate, which contains as much as 35 per cent of the zinc. Tailing from this circuit, includ-

FIGURE 1 — Mill and tailing disposal flowsheet at Western Mines Limited.

2458

ing the remaining 65 per cent of the zinc, feeds the primary zinc circuit.

Sodium cyanide is added to the copper-lead concentrate in the separation circuit, depressing the copper and producing a lead concentrate. As this depends on complexing of copper by the cyanide ion, significant levels of soluble copper cyanide complexes are present in the separation circuit tail. This is pumped to a 40-ft double tray thickener, which serves to separate the effluent containing cyanide and dissolved copper for subsequent treatment.

Underflow from the 40-ft thickener is reground and treated by flotation for recovery of copper concentrate. Copper circuit tailing reports to the secondary zinc circuit.

Zinc flotation consists of a primary circuit which handles the copper-lead rougher tail and a secondary circuit which treats the copper tailing. Secondary zinc tailing reports to the primary zinc circuit through a 24-ft thickener. The thickener overflow, containing cyanide and dissolved copper carried over from the copper circuit, is treated with the 40-ft copper thickener overflow prior to disposal. Primary zinc circuit tailing reports to the mine backfill cyclones for recovery of solids prior to disposal.

In addition to the main copper-lead-zinc circuits discussed above, a separate circuit is operated to process a small high-grade orebody containing high gold and silver values. The high-grade lead concentrate produced is blended with the regular lead concentrate prior to filtration. High-grade tailing reports to the main circuit for recovery of copper and zinc.

All concentrates are filtered, but only the copper and zinc products are dried. Copper and lead filtrates are pumped to the 40-ft copper thickener; the zinc filtrate reports to the 24-ft secondary zinc thickener.

TAILING DISPOSAL

The zinc circuit tailing, representing approximately 70 per cent of the total tailings volume, contains all of the solid waste. Approximately 50 per cent of these solids are removed by three 12-inch cyclones for use as mine backfill. The cyclone overflow, containing 7 to 10 per cent solids, flows by gravity through approximately 3 miles of 10-inch plastic pipe and a series of seven vertical drop boxes to a tailing raft located on Buttle Lake.

Waste effluents from the thickeners, containing significant amounts of dissolved copper and cyanide, report to the alkaline chlorination plant, details of which are discussed later. The treated effluent flows approximately 2 miles through a separate pipe line to the first drop box, where it mixes with the backfill overflow.

The combined tailings flow to a raft anchored several hundred feet offshore in the south basin of Buttle Lake. The tailings are discharged through a 32-inch submerged outfall, which extends vertically from the raft to approximately 80 feet below the surface (i.e., below the thermocline). Solids, with the aid of flocculant addition, settle to the bottom of the lake, which is from 100 to 150 feet deep at this point.

The tailing line is equipped with a flow alarm located at the lake. Thus, any interruption in flow due to line breakage can be acted upon immediately. A small emergency tailing pond is located near the plant for dealing with material discharged during breakdowns or maintenance of the tailing line.

EFFLUENT QUALITY

During the first six years of operation, pollution control procedures at Western Mines were adequate to meet the requirements of Permit No. 185. Emphasis at that time was placed on effective disposal of the solid material. Dissolution of heavy metals was not a problem, due to both the extremely low solubility of metal sulphides and the high pH of the circuit. Lead production commenced in June, 1970, but was very limited for the following 2½ years. Consequently, the presence of dissolved copper cyanide complexes was not significant until early 1973, at which time milling of ore from the Myra Falls mine had commenced. The high lead content of this orebody, plus more severe limitations on the lead content of the copper concentrate, necessitated full-time operation of the copper-lead separation circuit. The essential usage of cyanide increased substantially the levels of cyanide and dissolved copper in the effluent, because copper will complex with cyanide even under strongly alkaline conditions.

Investigations indicated that the most efficient and economical method of removing these contaminants from the effluent would be by alkaline chlorination. Construction of a plant for this purpose commenced in August, 1973, but numerous start-up problems prevented satisfactory operation until mid 1975.

Alkaline Chlorination

CHEMISTRY

The process of alkaline chlorination, whereby cyanide is oxidized to cyanate, is well documented. The most frequent application has been in metal finishing operations, such as heat treating, dipping, stripping, flashing and electroplating, all of which produce cyanide wastes. However, the volume of wastes in the above are considerably smaller than the 200,000 to 300,000 IGPD of effluent requiring treatment at Western Mines. Consequently, the scale had to be expanded considerably from operations discussed in the literature.

Two basic chemical reactions are involved, the first being the formation of cyanogen chloride, which is not pH dependent:

$$NaCN + Cl_2 \rightarrow CNCl + NaCl$$

At a pH of 10.5 or higher, obtained with lime addition (or caustic soda), the cyanogen chloride decomposes to cyanate:

$$2\,CNCl + 2\,Ca(OH)_2 \rightarrow Ca(CNO)_2 + CaCl_2 + 2H_2O$$

The above oxidation of a simple sodium cyanide solution requires a residence time of 15 to 30 minutes using 3.4 pounds of chlorine per pound of cyanide. However, the effluent originating from the copper-lead separation circuit contains 30 to 100 mg/l of dissolved copper, which, at the prevailing high pH, must be retained in solution as a cyanide complex, with copper being part of the anion. The anion may be cupricyanide $[Cu\ (CN)_3]^-$ or cuprocyanide $[Cu\ (CN)_2]^-$, although the latter tends to be more stable. Zinc will complex with cyanide in a similar manner, but this does not present a problem in the subject operation. Alkaline chlorination decomposes these complexes in an analogous manner to the simple cyanide, precipitating the metal cation as a hydroxide. However, the residence time for such reactions is much longer, possibly up to 1½ hours.

TESTWORK

Sampling throughout the plant confirmed that the overflow from the 40-ft thickener represented the primary source of cyanide and dissolved copper in the tailing effluent. This overflow contains 50 to 150 mg/l of cyanide and 30 to 100 mg/l of dissolved copper, depending on the rate of cyanide addition to the circuit. The latter varies with the copper and lead content of the ore, which can change considerably from day to day. The thickener underflow obviously contains similar concentrations of these pollutants, which are carried to some extent through the circuits to the zinc tailing. Sampling of the latter showed copper and cyanide levels of approximately 1 mg/l, which at the time were well below the permit requirements. This, plus the fact that chlorination of the entire tailing stream would be unfeasible, directed the program toward treatment of the 40-ft thickener overflow only.

Preliminary lab tests were conducted using calcium hypochlorite as a chlorinating agent. Although residual levels of cyanide and dissolved copper contained in samples of 40-ft-thickener overflow were reduced to acceptable values in these tests, the use of hypochlorite in a full-scale operation was deemed both inefficient and uneconomic.

A second series of tests was run on 500-gal. batches of 40-ft-thickener overflow. Chlorine gas was supplied from a 150-lb cylinder by means of a 100-lb-per-day chlorinator. It was assumed at this stage of the testing that the pH of the thickener overflow, at 10 to 11, would be sufficient to complete the reaction. Although cyanide was almost completely eliminated from the effluent by this procedure, the pH had dropped to approximately 3 at the end of each test cycle. Thus, lime addition to pH 12 was required to precipitate the dissolved copper.

The batch tests established tentative parameters for chlorine addition rate and retention time upon which a full scale treatment plant could be developed. However, it was decided to run a pilot-scale test concurrent with the design of permanent treatment facilities. In addition to evaluating the effects of a continuous operation on the entire effluent stream, the pilot operation served to maintain the cyanide and dissolved copper levels within acceptable limits in the interim.

Chlorine for the pilot-scale operation was supplied through two 500-lb-per-day chlorinators, each connected to a 1-ton chlorine cylinder. These were set up to feed chlorine directly into the 40-ft-thickener overflow line. The high pH of the effluent was again relied upon for alkalinity, and the time of travel down the 3-mile length of trailing line was assumed to be sufficient retention time. The high pH of the backfill plant overflow was deemed sufficient to precipitate the copper following destruction of the cyanide. The above operation ran for a 7-week period, during which a comprehensive 24-hour sampling program was conducted. Data collected indicated that 800 to 1000 lb per day of chlorine was required in order to maintain the cyanide and dissolved copper content of the tailings below the 1967 permit levels.

CHLORINATION PLANT

Construction of the chlorination plant commenced in mid August 1973. Following a continuing series of delays related to construction problems, slow equipment deliveries, etc., the plant was sufficiently complete to operate on a manual basis by December 1973.

Chlorination of the effluent takes place in three 10- by 10-ft fibreglass tanks, arranged in series to obtain a retention time of approximately 1½ hours for flow rates of 200,000 IGPD. Chlorine is delivered in 1-ton cylinders, which are connected to a manifold six at a time. Valving is such as to have three cylinders on stream and three on standby. The initial set-up included a 1000-lb-per-day chlorinator which drew chlorine gas directly from the cylinders. Controls included pH and ORP recorders, a magnetic flowmeter and an automatic chlorine changeover system. The latter, activated by a pressure switch, automatically switched to the standby set of cylinders when the operating set ran empty. As in the case of the pilot tests, it was assumed that the pH of the thickener overflow was sufficient for complete reaction, with copper precipitation taking place when the treated effluent mixed with the backfill overflow at the first drop box.

Operation of the chlorination plant over the first four months following start-up was less than satisfactory. Although levels of cyanide and dissolved copper ran marginally within the requirements of the 1967 permit, numerous operating problems were en-

TABLE 2 — Comparison of Western Mines' Permit Specifications and Monitoring Results

	MAXIMUM PERMIT LEVELS		AVERAGE RESULTS ON MONTHLY COMPOSITE TAILING EFFLUENT SAMPLES	
	Original 1967	Amended 1975	Jan.-June 1973 No Chlorination Plant	July-Dec. 1975 Chlorination Plant in Full Operation
Total Solids	135,000 mg/l	135,000 mg/l	*	70,517 mg/l
pH	6.5 - 8.5	6.0 - 10.0	7.7	9.74
Dissolved Copper	10.0 mg/l	0.3 mg/l	2.85 mg/l	0.08 mg/l
Dissolved Lead	—	0.1 mg/l	0.17 mg/l	0.06 mg/l

ountered. Concurrent with the above, the Pollution Control Branch notified Western Mines in April 1974 hat Permit No. 185 was to be amended. The limits f the amended permit are compared to those of the riginal in Table 2. Although the discharge at that ime was meeting most of the new requirements, the evels of cyanide and dissolved copper presented a roblem.

In light of these developments, a thorough study of he chlorination plant was made by both Western Mines and an outside consultant. As a result of the nvestigations, several modifications were made to he process. These are discussed below and are illustrated in Figure 2, which depicts the present plant ayout.

1. The assumption that the 40-ft-thickener overflow was sufficiently alkaline for the process was found to be incorrect. Apparently it is essential that the pH be maintained at 10.5 or higher, not only to ensure complete cyanide oxidation, but also to adequately precipitate the copper and eliminate any possibility of toxic cyanogen chloride emission. This had not been the case during the initial months of operation. Addition of chlorine to the effluent lowered the pH to approximately 3, thus contributing significantly to the inefficient operation encountered during this period. In addition, the acidity of the solution created corrosion problems, and the presence of cyanogen chloride gas was detected throughout the area.

   Provisions were made at the end of April 1974 to supply lime directly to the 40-ft-thickener overflow upstream from the chlorine addition point. It is added in excess to maintain the pH between 11 and 12. Manual control of the feed rate by means of a simple slotted weir box has proved both effective and trouble-free.

2. Under the terms of the amended permit, a substantial increase in the degree of cyanide and dissolved copper elimination was necessary. This required a 25 to 50 per cent increase in the chlorine addition rate. The capacity of the 1000-lb-per-day chlorinator was readily increased to 2000 lb per day by minor changes to the flow valve assembly. Operating data following this change indicated that complete cyanide destruction was effected at chlorine flow rates of 1200 to 1500 lb per day (assuming other operating parameters are correct). However, withdrawal of the compressed chlorine at these rates produced considerable heat loss due to the gas expansion. This in turn chilled the chlorine cylinders and contents, often to the point where the vapour pressure would drop sufficiently to substantially reduce the flow of chlorine. The situation was compounded when the ambient temperature fell below 50°F.

   The solution to the refrigeration effect noted above was a chlorine evaporator. This unit draws liquid chlorine from the cylinders and vapourizes it in a heated chamber, thus ensuring a continued supply of chlorine at the large flow rates required. An evaporator was ordered in May 1974 and, following a long series of unwarranted delays, delivery finally took place in March 1975. Operation continued in the interim on a less than satisfactory basis. Installation of the evaporator resulted in a substantial improvement in plant operation. The 8000-lb-per-day capacity of the unit is more than adequate to ensure a steady chlorine flow within the capacity of the chlorinator.

   Withdrawal of liquid chlorine and the necessary procedures involved in emptying cylinders, lines, etc., during tank changes precluded the use of the automatic changeover system. Therefore, the system was replaced with manually operated valves and a low-pressure alarm.

3. As noted previously, the original concept of effluent treatment was directed to the 40-ft-thickener overflow, which contains approximately 90 per cent of the residual cyanide and dissolved copper discharged from the separation circuit. Under the terms of the original permit, levels of these contaminants in the backfill plant overflow, carried over from the 40-ft-thickener underflow via the copper, secondary and primary zinc circuits, were not significant. However, with the advent of the permit amendments, steps were required to upgrade the quality of this stream. This was accomplished by diverting the secondary zinc circuit tail to a 24-ft thickener for decantation prior to treatment in the primary zinc circuit. The overflow from this thickener reports to the chlorination plant. This procedure has reduced the residual cyanide and dissolved copper in the backfill plant overflow to acceptable levels.

4. The availability of a sufficient and steady supply of chlorine made it possible to install an automatic control system, whereby the chlorine flow can be governed by the oxidation reduction potential (ORP) of the effluent. As ORP is based on the change from a reducing system (alkaline cyanide) to an oxidizing system (hypochlorite analogous to free chlorine), the proper millivolt setting for the ORP on the controller will ensure a sufficient supply of chlorine, within the capacity of the plant, to completely convert all cyanide to cyanate. Empirical determinations have indicated that optimum operating conditions are attained at an ORP setting of -600 mv at the prevailing pH of 11 to 12. The plant has operated on this basis since August 1975.

Current operation of the alkaline chlorination plant is fairly satisfactory, although problems have been encountered due to impurities in the chlorine supply. This has resulted in frequent plugging of lines, orifices, etc., in the gas dispensing system. A chlorine filter, installed in July 1976, appears to have alleviated the situation. Typical results attained by the plant following completion are given in Table 3.

Capital costs, including installation labour, totalled $107,000. Chlorine and lime addition, at 1.5 and 2.75 lb. per ton of ore milled respectively, account for most of the operating costs, which average $8,000 per month.

TABLE 3 — Elimination of Cyanide and Dissolved Copper - Average of Daily Samples Taken During September 1975

	Total Cyanide (mg/l)	Dissolved Copper (mg/l)
Chlorination Plant Feed	68.3	41.9
Chlorination Plant Discharge	0.13	0.14
Backfill Overflow	0.06	< 0.01
Total Tailings	0.07	0.02

Monitoring Program

MONITORING OF THE TAILING EFFLUENT

Chlorination plant feed and discharge, backfill overflow and total tailings are sampled and assayed daily. This is done primarily as a control function, and is supplemented with monthly samples of the total tailings, which are sent to an independent laboratory for more comprehensive analyses. The results of the latter are submitted to the Pollution Control Branch, who in turn perform independent sampling of the discharge several times per year. The improvement in tailing effluent quality following installation of the alkaline chlorination plant is illustrated in Table 2, which compares average monitoring results during the first half of 1975 to those of the last half of 1975.

Although the monitoring results have been generally acceptable, in many cases assays on identical samples, run at different laboratories, have differed markedly, often by as much as 1000 per cent. This cast considerable doubt on the validity of the entire program. Subsequent investigations indicated that lack of proper sample preservation prior to shipment to the assay lab was a significant cause of the discrepancies. Standardization of sampling, preservation and assaying procedures has resulted in a substantial improvement in the agreement of all results, except those of cyanide. The latter is still under investigation.

The sampling and assaying procedures described above are supplemented by 96-hour LC 50 static bioassays, performed on the tailing effluent twice per year. However, these were only initiated in August 1975, and the data are too limited to be conclusive.

MONITORING OF BUTTLE LAKE

The long-term effects of discharging tailings into Buttle Lake is assessed by routine sampling of both the lake water and fish. A comprehensive set of analyses is performed annually on the former and results are compared with those obtained concurrently on all creeks entering the south basin of the lake. Fish specimens are collected three times per year near Western Mines' tailing raft and both flesh and liver are analysed for copper, lead, zinc and mercury. The data collected over the years does not indicate any increasing trend in levels of the pollutants tested.

Conclusions

The implementation of alkaline chlorination at Western Mines Limited has been successful in reducing cyanide and dissolved copper controls in the mill tailings to acceptable levels. Further, the extensive data collected over the past ten years by both the company and various regulatory bodies indicate that the discharge of tailings into Buttle Lake has not had any adverse effect on the quality of the water, either for aquatic life or domestic purposes.

The author wishes to acknowledge the substantial contribution made by H. E. Jackson, senior research chemist, Cominco Ltd., who acted as a consultant to Western Mines Limited during the development of the alkaline chlorination plant .

SUPPLEMENT TO "POLLUTION CONTROL AT WESTERN MINES' MYRA FALL OPERATION"

INTRODUCTION

The following is an update of the earlier paper published September 1977 in the Canadian Mining & Metallurgical Bulletin. The purpose is to review the operation of Western Mines' alkaline chlorination over the past five years with regard to maintenance, operating effectiveness, cyanide levels and costs.

OPERATION AND MAINTENANCE

Overall operation of the alkaline chlorination plant over the past five years can be considered generally satisfactory. The only operating problem of any significance has been frequent plugging of lines, orifices, etc., in the gas dispensing system. As noted in the previous paper, the situation is caused by impurities in the chlorine supply. Although samples have been submitted to the supplier, the source of impurities has not been identified other than the fact that they are organic in nature. However, installation of a chlorine filter in 1976 alleviated the situation considerably. Disassembly and complete cleaning of the chlorinator is now required once per year, rather than once per month as was necessary prior to filter installation.

During the first years of operation, chlorine addition rates of 1200 to 1500 lbs. per day were adequate to reduce cyanide in the effluent to satisfactory levels. However, ore changes over the past twelve to eighteen months have necessitated increases in cyanide addition rates of up to 30%. This, in turn, has increased the chlroine requirements to 1800/2000 lbs. per day (and higher on occasion). In addition to continuously taxing the chlorinator to its limit, these rates have considerably shortened the life of the unit. Thus, at the time of writing, a complete rebuild or replacement of the chlroinator will be necessary within six months. The latter is the logical choice in view of the increased loading, and a 4000 lb./day unit has been budgeted for 1981.

The chlorine evaporator, with a capacity of 8000 lbs./day, has presented very few problems. Other than minor electrical repairs and replacement of one or two gauges, this unit continues to operate trouble-free. The evaporator and all related piping was completely disassembled, cleaned and inspected in October 1980 and no evidence of corrosion or deterioration of any kind was observed.

CYANIDE LEVELS

The alkaline chlorination plant, given sufficient quantities of chlorine and lime, is capable of reducing both dissolved cyanide and dissolved copper to "trace" levels . The effluent from this plant is further diluted upon mixing with the remainder of the tailing from the backfill plant (essentially Cu and CN free). This ensures that the final tailing discharged to the lake, under normal operating conditions, is capable of meeting the permit requirements.

.../2

SUPPLEMENT TO "POLLUTION CONTROL AT WESTERN MINES' MYRA FALLS OPERATION"

Although the alkaline chlorination process will effectively eliminate dissolved cyanide, problems have been encountered from time to time with fairly high "total" cyanide levels in the chlorination plant discharge. The explanation for this would appear to be the formation of insoluble ferrocyanides due to the presence of ferrous iron in the ore. These ferrocyanides are highly stable and are not amenable to treatment by alkaline chlorination. However, due to the extreme stability and very limited occurrence of these compounds, it is recognized that they do not pose a threat to the environment.

As noted in the original paper, assaying for cyanide continues to be unreliable. The problem is due both to the difficulty in obtaining uniform, representative samples of a slurry and the fact that subsequent assays are unreliable as a result of interference from a number of constituents present in the effluent. To date, this problem has not been resolved.

COSTS

Operating costs by the end of 1980 were averaging $13,000.00 per month, and increase of roughly 65% over the 1976 costs noted in the original paper. Chlorine, at approximately 1.8 lbs. per ore ton accounts for 80% of the above, with lime at 2.7 lbs. per ore ton making up the balance.

Maintenance costs to date have averaged under $3,000.00 per year, although as noted earlier extensive costs will be incurred in 1981 for replacement of the chlorinator.

NORANDA GREY EAGLE MINES ALKALINE CHLORINATION

NORANDA GREY EAGLE MINES, INC.

Noranda Grey Eagle Mines, Inc. at Happycamp, California, operates a 120 USgpm alkaline chlorination plant to treat excess tailings solution from a 500 stpd gold cyanidation plant.

According to a report to the California Regional Water Quality Control Board dated September 1983 the existing alkaline chlorination plant treats decant solution containing:

200 - 450 mg/l Cu
150 - 360 mg/l CN (free).

A second, larger cyanide treatment plant was under consideration to treat seepage below the dam wall. For this application both alkaline chlorination and SO_2-Air treatment were considered. However, for the purposes of this report, only the existing plant is discussed from the point of view of some of the difficulties that were encountered which appear similar to those reported elsewhere - (notably at Scottie Gold Mining and Carolin Mines).

This plant uses chlorine and caustic as reagents. After metal cyanide complexes are decomposed the metals precipitate as hydroxides and are settled in a clarification step. For final polishing a filtration step is used before pumping treated effluent to a land application site.

"Problems with plant operation have resulted from scale buildup in pumps, from ferric chloride plugging the chlorine system, from clarifier carryover and from filter mechanical problems."

Cyanide and metals loading in tailings decant have been higher than anticipated. Copper in the ore has been high and correspondingly higher cyanide dosages in the mill have been used. As a result, caustic and chlorine demand have been high and solids production, primarily a copper precipitate have been greater than that for which the original clarification and filtering plant were designed.

The plant supply pump (on a barge in the tailings pond), chlorine injector pumps and filter supply pumps require periodic cleaning of a scale buildup. The scale is believed to be a copper compound, likely a hydroxide. The scale is tenacious, requiring scraping or power wire brushing for removal, and at times builds up in sufficient thickness to stop pumps or reduce pump output. An anti-scaling agent was being investigated and preventative maintenance upgraded.

The chlorine system uses liquid chlorine drawn from a steel bulk storage tank. Chlorine forms ferric chloride in the presence of steel and moisture and causes a buildup in the chlorine evaporators and chlorinator components. Manufacturers recommend cleaning

components twice annually. With the very high chlorine throughput, however, monthly maintenance was necessary. Moisture inputs to the system and problems with impurities were investigated as sources of maintenance problems.

Controls have been made more responsive by moving oxidation-reduction-potential (ORP) probes to the chlorine reaction tanks. Initially the probes were remote from the tanks for safety reasons. However, the pH control system maintains pH consistently at proper levels, and the new location should not introduce safety risks. Scaling of the pumps supplying sample water to the remote probe location was the root of the problem.

The clarification facility has been overloaded with solids from the high levels of metal hydroxide sludge. As a result, the flocculation basin used to become plugged by settled sludge.

The clarifier portion experiences some carryover of small precipitate sludge particles. It was believed that the clarifier capacity might have been too small for the quantity of precipitate and clarifier expansion was under investigation.

Scaling of small orifices in the clarifier has resulted in periodic maintenance. Enlarging the orifices has been recommended.

Filtration was provided to polish the effluent. At times the filters were not needed and copper levels could be reduced sufficiently in the clarifiers. Clarifier modifications were to be made to increase the efficiency and reduce the need for filtration. Valve scaling and backwash on the filter system had aso presented maintenance problems. The manufacturer-supplier was investigating system modifications to improve reliability.

A Noranda internal report dated 3 June 1983 appeared in the compilation of data presented to the California Regional Water Quality Control Board showing that test data indicated that available cyanide and metals are equally well removed from the slurry by alkaline chlorination as by the SO_2-Air process at comparable reagent consumptions. However, the SO_2-Air process was more successful at reducing CN_T results due to ferrocyanide removal as discussed below.

Since the above status was established in 1983, the cyanide detoxification plant problems at NGEM have been successfully sorted out, but details were not pursued.

NORANDA RESEARCH CENTRE

INFORMATION MEMORANDUM 3 June 1983

cc:

FROM: M. Wasserlauf

SUBJECT: NORANDA GREY EAGLE MINE - PROJECT N-8321-3B - DESTRUCTION OF CN IN TAILINGS SLURRY

SUMMARY

Bench-scale tests conducted at the Noranda Research Centre indicate that Grey Eagle tailings can be detoxified with CN levels of <3 mg/L in the treated effluent. While SO_2 treatment removes the CN almost completely, alkaline chlorination resulted in a total CN residual of approximately 30 mg/L, due probably to iron cyanide complexes which are not removed by chlorine. Free cyanide levels in both cases were <1 mg/L CN in the effluent.

Treatment alternatives evaluated included detoxification of existing tailings (40% solids), as well as dewatering to 60-65% solids using thickeners or filters, then detoxifying. Due to the lower CN loading, the latter alternatives would lower operating costs by a half.

Additional work is on-going to evaluate stability of metals (Cu, Zn, Fe) in the detoxified tailings under varying pH conditions, and this work will be reported later.

1. INTRODUCTION

Noranda's Grey Eagle Mine discharges 500 TPD of tailings solids in a slurry containing 40% solids. Results of CN destruction tests conducted at the Noranda Research Centre with tailings made from the Grey Eagle ore were reported previously([1]). This memorandum presents results of tests conducted with actual mill tailings.

2. TAILINGS CHARACTERIZATION

Samples of Grey Eagle tailings were received at the Noranda Research Centre on May 24, 1983. Tests on the tailings yielded the following characterization:

RECEIVED JUN 7 1983

pH = 10.6
% solids = 39.2 W/w
Pulp density = 1.33
Cyanide in decant :
= 1700 mg/l Total CN (Picric acid)
= 1125 mg/L Total CN (distillation & CN electrode)
= 750 mg/L Free CN (CN electrode)

Cyanide in pulp = 1171 mg/L Total CN (distillation & CN electrode)
Thiocyanate = 365 mg/L CNS
Thiosalts = Not detected

3. CYANIDE BALANCE

Based on the above values, a cyanide balance can be computed as follows:

- Water in Tails = $\frac{500 \text{ T solids/day}}{60.8 \text{ \% water content}}$ = 822 T/day

- CN content: Due to CN: = 1125 mg/L
  Due to CNS: 365 mg/L X $\frac{26 \text{ (M.W. of CN)}}{58 \text{ (M.W. of CNS)}}$ = 163.6 mg/l
  1289 mg/L

CN in tails = 1289 mg/L X 822 T water/day
= 1.06 T CN/day (both CN & CNS)

This can be expressed as 2.0 t NaCN/day
or 8.0 lb NaCN/ton ore treated

This appears to agree with current NaCN useage in the mill.

4. CN TREATMENT TESTS

4.1 Methodology

Tests for CN destruction were carried out on 500 ml samples of magnetically stirred Grey Eagle tailings. Two methods were tested:

- SO_2 destruction: solutions of 20% Na_2SO_3 were added to the tailings pulp samples under variable test parameters, including SO_2:CN ratio, pH, added Cu concentration. A constant aeration rate of 1L/min was maintained.

- Alkaline chlorination: solutions of NaOCl (5.9% Cl_2) were added to the tailings pulp samples. Main test parameter was Cl_2:CN ratio, with pH maintained at 9 to 9.5.

Samples were taken at 0.5, 1, 2 h, with some also taken 24 h later. Total CN was analyzed by the picric acid, and distillation methods, with free CN analyzed by the specific ion electrode. Thiocyanate analysis was as per APHA Standard Methods.

4.2 SO_2 Results

Results of the SO_2 tests are presented in Table I. Based on the data, the following conclusions can be drawn:

TABLE I

NORANDA GREY EAGLE MINE

Results of SO_2 Tests

Time (h)	Parameter	Control (No SO_2, No Cu)	SO_2:CN ratio (without Cu added)				SO_2:CN ratio (with 100 mg/L Cu added)		
			3.75	7.5	11.25	11.25	11.25	11.25	15.0
0.5	pH	8.5	11.0	11.1	11.0	8.5	10.9	8.5	8.5
	Total Cn (P) (mg/L)	1650	790	290	195	121	95	26	23
	Free CN (mg/L)		150	88	60	37	22	13	13
	CNS (mg/L)								
1.0	pH	8.5	11.0	11.0	11.1	8.5	10.9	8.5	8.5
	Total CN (P) (mg/L)	1625	605	255	180	125	99	23	23
	Free CN (mg/L)		125	86	60	17	25	1.5	12
	CNS (mg/L)								
2.0	pH	9.5	10.8	10.8	11.0	8.5	10.9	8.5	8.5
	Total CN (P) (mg/L)	1388	450	80	80	<1 mg/L	30	3.0	2.5
	Free CN (mg/L)		94	23	34	<1 mg/L	12	1.1	1.2
								305	115
20.0	Total CN (P) (mg/L)							<1.0	<1.0
	(D) (mg/L)								0.25

P = picric acid
D = distilled

4.2.1 Reagent requirements: Reagent requirements are about 11 lb SO_2/lb CN.

4.2.2 Reaction pH: A pH of 8.5 is required. Tests at pH of 11 (the pH of tails and Na_2SO_3) resulted in excessively high CN residuals (>80 mg/L).

4.2.3 Copper additions: There appears to be no advantage to the use of supplemental copper.

4.2.4 Reaction time: The CN destruction reaction with SO_2 were found to proceed quite rapidly initially, with a removal of roughly 1000 mg/L at optimal conditions in the first 30 min. The removal of the remaining CN was, however, much slower. Thus, it appears that a reaction time of 2 h is necessary.

4.2.5 Aeration: Air addition to the control sample (1L/min) resulted in a 16% decrease in CN levels after 2 h.

4.3 Cl_2 Results

Results of alkaline chlorination tests are presented in Table II. These data provide the following conclusions:

4.3.1 Reagent Requirements

Alkaline chlorination provides total removal of CN amenable to chlorination with a residual of <1 mg/L CN (by picric acid method) at a CL_2/CN ratio of between 12 and 15.

4.3.2 CN Removals

Analysis by distillation indicates a residual of about 30 mg/L CN, probably due to iron cyanide complexes, which are not destroyed by chlorination.

4.3.3 Reaction Time

Test results indicate rapid reaction kinetics, with no changes in parameters monitored after 30 min.

5. FORMS OF CN

CN analysis were conducted by distillation on both tailings pulp, and decant samples both before and after treatment. In all cases, results of these tests (below) indicated similar values, suggesting that CN is present entirely in the liquid phase.

TABLE II - NORANDA GREY EAGLE MINE

RESULTS OF ALKALINE CHLORINATION TESTS

Time (h)	Parameter	Cl_2:CN Ratio			
		3.75	7.5	11.25	15
0.5	pH	9.7	9.6	9.1	8.6
	Total CN (P) (mg/L)	950	210	7.5	<1.0
	(D) (mg/L)				29.6
	Free CN (mg/L)	300	100	2.5	<1.0
	CNS (mg/L)				<1.0
1.0	pH	9.8	9.7	9.3	
	Total CN (P) (mg/L)	950	270	7.0	
	Free CN (mg/L)	300	120	1.9	

(P) = picric acid

(D) = distilled

Sample	Total CN (mg/L) Pulp	Decant
Tailings before treatment	1171	1125
SO_2 Tests (SO_2:CN = 15:1)	0.25	<0.25
Cl_2 Tests (Cl_2:CN = 10:1)	30.0	29.6

6. TREATMENT SCHEMES

Three principal treatment schemes can be considered:

Scheme No. 1 - End of pipe treatment of tailings (40% solids w/w) - Figure 1.

Scheme No. 2 - Thickening of tailings to 60% solids (as indicated by Noranda Research settling tests), treatment of thickener underflow for CN, recycle of thickener overflow to mill - Figure 2.

Scheme No. 3 - Filtering of tailings to 65% solids (as indicated by SRK tests), reslurring of coke; and treatment for CN, recycle of filtrate to mill - Figure 3.

Based on the most recent data, the approximate mass balances are as follows:

Scheme 1	Scheme 2	Scheme 3
166 gal/min mill tailings pulp @ 40% solids = 822 T/day water @ 1125 mg/L Total CN	Thickener underflow @ 60% solids = 333 T/day water @ 1125 mg/L total CN	Filter coke @ 65% solids = 270 T/day water @ 1125 mg/L Total CN
= 1850 lbs/day CN	= 750 lbs/day CN	= 607 lbs/day CN

For each scheme, CN destruction by alkaline chlorination, and SO_2 treatment can be considered.

DISCUSSION

Based on the water chemistry shown in the following table it is concluded that a large part of the scale and precipitate is likely to be a $CaCO_3$ precipitate which results when the pH is raised over 7.3.

$$HCO_3^- + OH^- \rightleftharpoons CO_3^= + H_2O$$

$$Ca^{+2} + CO_3^= \rightleftharpoons CaCO_3$$

CALCIUM AND BICARBONATE SOLUBILITY VS pH

Source: HEM (1970)

–Equilibrium pH in relation to calcium and bicarbonate activities in solutions in contact with calcite. Total pressure 1 atmosphere; temperature 25°C.

200 mg/l $CO_3^=$ is already present in solution as bicarbonate, but additional carbonate may be generated if excess chlorine is applied with a long enough residence time for Stage 2 reactions to take place. Each 1 g CN^- could theoretically generate just over 2 g $CO_3^=$. Consequently 260 gm/l CN^- could generate 520 gm/l $CO_3^=$ making a total of 720 gm $CO_3^=$/l assuming all cyanide is reacted to completion through Stage II reactions.

Even with the 200 ppm HCO_3^- already in solution, at pH 6.9 this solution is already saturated with Calcium at 260 mg/l. According to the diagram shown on page 134 of HEM (1983) at pH 9.5 Calcium concentrations as low as 1 ppm would be saturated, and about 400 mg $CaCO_3$ per l or more could be expected to precipitate. No doubt the copper released by CN decomposition coprecipitates as $Cu(OH)_3$.

There are two possible solutions to the scaling problem. First is to employ a $CaCO_3$ scale inhibiting reagent. The second is to remove CO_2 from solution ahead of addition of the NaOH and chlorine which would involve an additional step but would also reduce NaOH consumption.

CYANIDE DETOXIFICATION AT SUPERIOR MINERALS, STIBNITE, IDAHO

At Superior Mines Yellowknife Idaho heap leaching operation, cyanide must be rinsed from the leached heaps and the heaps then detoxified. Also the leached heaps are moved to a tailings area and detoxified again using a $Ca(OCl)_2$ solution prepared on the site from pebble lime and liquid chlorine.

The 3000 stpd heap leaching operation is located at a high altitude in steep mountainous terrain alongside the Salmon River that is the headwaters for an important salmon fishery downstream.

The main environmental aspects of concern are to prevent cyanide and heavy metals from getting into the stream. The second concern is to prevent suspended solids from getting into the creek.

HEAP LEACHING

The 10 feet high heaps of ore crushed to 1½" X 0 are 1.5 lbs lime added per ton ore during stacking. The 10' heaps are subjected to 50 day leach cycles made up of:

10 days to build the heap
20 days to leach
10 days to wash the heap
10 days to remove the heap.

CYANIDE DESTRUCTION

The 10 day wash phase is broken down further as follows:

2 days drain after leach
6 days wash with $Ca(OCl)_2$ solution
2 days drain after washing.

By raising the pH to pH 12-13 it is possible to greatly speed up the detoxification step to 6 days. When the solution is applied at pH 10, it took 22 days to get "off" solution down to 0.2 ppm CN.

Solution is applied to the 200' X 250' heaps at a rate of 0.3 gph/ft^2 (0.005 gpm/ft^2) i.e., 2500 lb per minute per heap.

CN destruction if found to proceed faster at pH 12-13. Solution from the special reservoir of cyanide neutralization solution at pH 12-13 is applied by spraying it through the same distribution system as was used to spray leach solution onto the heaps.

One problem is that grit in the pebble lime used to make $Ca(OCl)_2$ sometimes clogs the sprinklers. This could possibly be avoided by installing Bateman Filtomat units into the line. Operating staff turn off the line supply temporarily allowing Cl_2 to reduce the solution pH which, more often than not, unclogs the sprinklers.

CALCIUM HYPOCHLORITE ADDITION PARAMETERS

1.25 lb $Ca(OH)_2$ is added per lb of Cl_2
4000 lb Cl_2/day are added @ 240 USgpm
i.e., 12 st Cl_2 over 6 days per 30,000 t heap = 0.8 lb Cl_2/t heap
@ a price of \$360/t Cl_2 delivered this works out to US \$0.14t ore.

CHLORINE PRICE

\$360/t Cl_2 = \$0.18/lb Cl_2

This compares very favorably with the quoted cost of \$1.30/lb $Ca(OCl)_2$ @ 60% effective Cl_2 strength.

At all times 3.5t $Ca(OCl)_2$ are on standby in case the $Ca(OCl)_2$ manufacturing system shown in the sketch above should fail.

Cl_2 is supplied by Pennwalt in 1 ton cylinders. Ten cylinders were hooked to the Cl_2 gasifier for automatic changeover should any one become empty. Pennwalt also supplied a Cl_2 metering device.

MONITORING

CN^- levels are monitored at regular intervals in the "off" solution during chlorination.

CN^- is also monitored at ppb levels in solutions drawn from monitor wells and analysed using a HACHMETER model DR100 colorimeter Model 41100.

HACH CO.
Box 389
Loveland, CO

FREEZE PROTECTION

The heaps are detoxified before the leached material is placed on the tailings dump. It is also deemed necessary to detoxify any heap that may be in the process of being leached when a sudden freeze occurs. If the frozen heap were to be left through the winter with CN^- still in it, this could leak during the spring runoff.

In case of such a freeze, the detoxification system is fitted with a 50 HP Boiler and heat exchanger to heat the solution which is pumped to the heap at 240 gpm.

PEBBLE LIME

By converting from NaOH to $Ca(OH)_2$ for pH control on the heap it was found that NaCN consumption dropped from 1.5 lb/t ore to 0.2 lb NaCN/t ore. The reason for this is suspected to be that NaOH solubilizes iron or other base metals which consume CN^-.

Pebble lime is used for the $Ca(OCl)_2$ manufacturing in preference to slaked lime which would blow around.

Because pebble lime introduces grit into the circuit which clogs sprinkler orifices, some sort of grit screen would be appropriate in the line.

DETOXIFICATION Pond

A 1 mm gallon pond is used to contain the neutralization (detoxifying) solution.

CYANIDE

So sensitive is the stream considered to be to cyanide that from August 1 to September 15 no chemical reagents are hauled along the roadway to the plant to avoid any possibility of an accidental spill into the stream.

More information on the CN^- destruction system can be requested from:

DUVAL CORPORATION, BATTLE MOUNTAIN OPERATIONS

Alkaline chlorination of cyanide tailings pulps is known to be practiced at Duval Corporation's Battle Mountain Operations where 3450 mt/d ore in a 35-50% solids slurry is detoxified. After treatment the pulp flows via several drop boxes to the valley below where the tailings pulp are discharged to the desert floor. Because of the high copper content it is unlikely that this solution could be recycled to a great extent without causing metallurgical headaches.

A description of the tailings treatment plant is included in the Randol Phase I report "Innovations in Gold and Silver Recovery" which was written before expansion of the Battle Mountain CIP plant. The data therefore refers to a 2720 mt/d operation. In June 1984 management declined to discuss their tailings treatment and mention of the subject is not made by TODD & ANDERSON(1984) in their paper describing the operation although they did indicate that the free cyanide residual after leaching ranges from 200-500 mg CN/l with high copper cyanide levels.

TAILINGS DISPOSAL

After CIP, BATTLE MOUNTAIN tailings are treated in a final contactor known as their Tank #7 in which chlorine and lime are added to destroy residual cyanide.

Tailings then flow down a high density polyethylene pipe to a tailings dam at the base of the mountain. There are about twenty drop boxes enroute.

Cyanide addition in the leaching circuit was adjusted to maintain 1 lb free NaCN per ton solids in the final pachuca, i.e., 500 PPM NaCN. Because of copper and iron in the ore, considerable quantities, cyanide complexes of these metals will also be present. In the CIP effluent pulp, about 10 PPM soluble copper is measured which will be present as the complex $[Ca(CN)_3]^{=}$.

Oxidation with chlorine is designed to destroy all free cyanides according to the following reactions:

$$NaCN + NaOCl = NaCNO + NaCl \quad (1)$$

$$Cl_2 + 2NaOH = NaOCl + NaCl + H_2O \quad (2)$$

$$2NaCNO + 3NaOCl + H_2O = CO_2 + N_2 + 3NaCl + 2NaOH \quad (3)$$

Reaction (1) is accelerated by increasing pH being completed within minutes at pH 10 or above.

Reaction (3) is accelerated by reducing pH being extremely slow at pH 10, but only 10 minutes at pH 8. Below pH 7, the cyanate (CNO) converts to ammonia.

BATTLE MOUNTAIN generate OCl^- using lime and chlorine rather than soldium hydroxide.

A suitable effluent treatment plant controlling pH and redox conditions has been designed by:

POLLUTION CONTROL SYSTEMS
1295 West 78th Street
Cleveland, Ohio 44102
(216) 651-7703 or (216) 251-3430

Chlorine consumption for cyanide destruction in tailings amounts to 3700 US gallons per day (20 st) and costs $5,000/day. An additional 40 lbs of lime per ton of ore is consumed in the OCl^- generating system. Another source of data showed chlorine consumption at 16 to 22 lbs per ton ore.

3700 US gal./d 40,000 lb Cl_2/day$5000/d
132 tons/d lime @ $65/st $8500/d

12.12 lbs Cl_2 per ton ore @ 12.54/lb Cl_2 $1.52/ton ore
40.0 lbs lime per ton ore @ 3.34/lb Cl_2 $1.32/ton ore

Cost of Reagents for Tailings Treatment $2.84/st ore

A small EIMCO filter has been installed to test recovery of cyanide solution from CIP tailings. This would reduce the amount of chlorine required to destroy cyanide, and might hopefully recover reagent values for recycling.

One aim of the belt filter is to reduce the soluble copper levels in the tailings since copper ties cyanide up, which reports as free cyanide in the silver nitrate titration.

Virtually nothing is known about the belt filter test work or how it was applied, since this was installed too late for review in the Phase II Report. The belt filtration test work for cyanide tailings treatment is an aspect of definite interest for further followup.

RANDOL INTERNATIONAL LTD believes that the BATTLE MOUNTAIN plant may be an ideal location to test other cyanide destruction techniques identified as part of this investigation and discussed in the secton of this report dealing with effluents and tailings disposal.

DETOUR LAKE, ONTARIO

This new mine, mill and CIP gold recovery plant operates currently at 2500 mt/d ore throughput with announced plans to expand to 4400 mt/d by 1987.

It is believed that after CIP the tailings pulp is treated by alkaline chlorination before pumping to the pond.

It is not yet known what the cyanide levels are before or after treatment.

Produce Sodium Hypochlorite (NaOCl) on-site with the PEPCON TYPE PF System

Chlorination, Disinfection, Odor Elimination, Slime and Marine Organism Control for • Municipal Water and Wastewater Treatment Plants • Industrial Plants • Chemical Manufacturers • Food Processors • Power Plant Circulating and Service Water Systems • Cooling Towers • Offshore Platforms

Type PF parallel flow vertically-mounted cells for sea water and special brine (purchased salt) applications

PEPCON 280-cell system for producing 5,600 lbs. per day of sodium hypochlorite for final effluent disinfection at the Waterloo, Iowa Water Pollution Control Plant (Average plant flow—20 MGD; peak flow—35 MGD). Left—Cell modules pre-assembled in convenient rows for easy installation, ready for shipment. Right—Cells installed at Waterloo, Iowa.

A safe and dependable alternative to liquid chlorine (Cl^2) or commercial hypochlorite

The advanced PEPCON System is economical to operate and simple to maintain. As pictured above, it is built around an efficient electrolytic system, the heart of which is the inexpensive, long life, PEPCON cell with its special anode, operating at low D.C. voltage. Simply supply inexpensive salt, or seawater, to the PEPCON unit to produce the amount of NaOCl you require.

Conversion of chlorides to a safe, dilute NaOCl solution takes place entirely within the unique PEPCON cell. The hazards and the expense of transporting, storing and handling chlorine are eliminated.

Safety, reliability, and economy of the PEPCON electrolytic cell have been proven by more than fifteen years of operating experience.

PEPCON 32 cell seawater system for producing 800 lbs. per day of sodium hypochlorite for control of marine organisms for an overseas waterflood project.

Sodium hypochlorite generation—
From 10 pounds per day to any required amount

Typical Flow Diagram for PEPCON NaOCl-from-Brine System with Recycle, Cooling and Product Storage.

Typical Flow Diagram for NaOCl-from-Seawater System with Recycle and Product Storage

How the PEPCON system functions

Prepared brine or seawater passes through the PEPCON cells where it is electrochemically transformed into sodium hypochlorite (NaOCl). The hypochlorite solution produced is either discharged directly into the receiving stream or to storage.

The maximum concentration of NaOCl generated can be varied by selection of a system designed to operate on a once-through, recycle, or recycle with cooling basis.

Economics of PEPCON method of sodium hypochlorite production

For brine systems the system design can be varied to take best advantage of the relative costs of salt and electric power at the specific jobsite. Safe hypochlorite is usually produced at a cost competitive with liquid chlorine delivered in tank cars or ton cylinders.

For "once-through" seawater systems the power required for the electrolytic cells typically ranges from 2.00 to 2.75 kilowatt-hours per lb. of NaOCl generated, depending on the salt content and temperature of the seawater. If recycle or solution cooling is incorporated in the system design an additional small amount of power is required.

Production cost for PEPCON hypochlorite, generated on-site, is well below that for hypochlorite purchased from outside sources.

Other PEPCON electrolytic systems

- Type SF Hypochlorite Generators for most brine (purchased salt) applications.
- Direct "flow-through" treatment for deodorization of digester supernatants, centrates, and filtrates, and for disinfection and odor control of industrial and municipal effluents.
- OdorMaster single stage and multiple stage gas odor control systems.

Litho in U.S.A. Form No. 891 Rev. 7/1/81
U.S. and Foreign Patents and Patents Pending

Features:

- Modular design permits sizing for any required NaOCl production.
- Designed for trouble-free operation. Changing a cell is like changing a fuse. It is never necessary to return a PEPCON cell to the factory for replating. When required an inexpensive replacement anode is simply inserted in the reusable cathode by operating personnel at the jobsite.
- Cells are factory mounted to corrosion resistant fiberglass structural supports, for easy field installation.
- Operation is at a safe 5-7 volts D.C. per module. Rectifiers are equipped with polarizers to prevent cell damage from galvanic action during routine "system-off" periods.
- Choice of system control and injection methods.
  (1) Produce NaOCl at varying concentrations, paced by a plant flowmeter or residual chlorine analyzer, and inject directly into the stream to be treated.
  (2) Produce and store NaOCl at a constant concentration, with injection from storage controlled by a timer, flowmeter, or residual chlorine analyzer. Automatic on-off generation system operation in response to level sensors in the storage tank.

1 INTRODUCTION

1.1 General

Following submission of an unsolicited proposal to Supply and Services Canada in August, 1981, Ker, Priestman & Associates Ltd. (KPA) of Victoria, B. C. were awarded Contract No. 43SS.KE145-1-0497 in January, 1982.

The unsolicited proposal was formulated in response to a recognized need by both industry and the regulatory authorities for a better understanding of the capabilities and limitations of the alkaline chlorination process, which was coming into common usage in the Canadian gold milling industry, as a treatment method for cyanide-bearing effluents.

The program was sponsored by the Environmental Protection Service of Environment Canada; the scientific authority assigned to the project was:

Mr. A. Zaidi, P. Eng. - Process Development Engineer,
Wastewater Technology Centre,
Environmental Protection Service,
Environment Canada,
Burlington, Ontario.

The main Ker, Priestman & Associates Ltd. personnel involved in this study were:

J. B. Brodie, P. Eng.- Manager, Environmental Division
R. Wilkes - Senior Technician

Also involved, during the later stages of the program was:

L. Whittle - Senior Process Development Technologist,
Wastewater Technology Centre,
Environmental Protection Service,
Environment Canada,
Burlington, Ontario.

1.2 Objectives

The objectives of the program were to:

(a) determine the optimum conditions for the destruction of cyanide and other contaminants, by the alkaline chlorination process

(b) establish a valid data base relative to the effluent quality which can be routinely achieved by alkaline chlorination under optimum conditions

(c) make recommendations regarding operating controls, procedures and equipment.

1.3 Scope

The program was divided into four phases:

Phase 1 was a preliminary review of the mechanical and chemical operation of the systems to ensure that they were functioning properly. This phase was carried out by Harry Jackson, an independent consultant, under separate contract. Mr. Jackson's conclusions and recommendations are not included in this report.

Phase 2 involved a series of tests under different process conditions to determine the optimum conditions for alkaline chlorination.

Phase 3 was the routine collection of data, with each system operating under previously-established optimum conditions.

Phase 4 was the interpretation of data and report preparation.

The mines studied were identified, for the purpose of anonymity, as Mines A, B, and C. The study of Mines A and B took place between February and October, 1982, followed by the study of Mine C between December, 1982 and February, 1983.

2 CHEMISTRY

2.1 Process

A simplified block diagram outlining the main steps in the process for the recovery of gold from its ores, shown in Fig. 1, consists of the following operations:

a) crushing and grinding the ore
b) flotation of a sulfide concentrate containing the gold (Mine C only)
c) leaching the ground ore or flotation concentrate with an alkaline solution of sodium cyanide to dissolve gold from the gangue
d) filtering and washing the leached residue to separate the pregnant solution from the solids
e) recovering gold from pregnant solution by the Merrill Crowe process
f) treatment of effluents by alkaline chlorination
g) discharge of effluents to a tailings pond.

Cyanide-bearing wastes originate in gold mills from a variety of sources including, most commonly, the barren bleed solution and the cyanide leach residue. The latter is generally not treated because the presence of solids interferes with chlorination. Free cyanide, metal-cyanide complexes, thiocyanate and dissolved metals represent the major contaminants.

The following terms and symbols are pertinent:

CN_T total cyanide
CN_W weak-acid dissociable cyanide*

---

* The term "weak-acid dissociable cyanide" refers to an analytical method similar to that used for total cyanide, except that the conditions in the distilling flask are such as to encourage breakdown of nearly all cyanide complexes except the most stable, viz. those of iron and cobalt. See Section 3.1.

2.2 Alkaline Chlorination

Alkaline chlorination refers to the controlled addition of chlorine or hypochlorite at a high pH (10 - 12) for the oxidation of free cyanide and metal-cyanide complexes to the cyanate form or further to bicarbonate and nitrogen, by the following reactions:

$$CN^- + Cl_2 + 2OH^- \rightarrow CNO^- + 2Cl^- + H_2O$$
$$2CN^- + 5Cl_2 + 10(OH)^- \rightarrow 2HCO_3^- + N_2 + 10Cl^- + 4H_2O$$

A number of ancillary reactions are known to occur including the oxidation of thiocyanate to cyanate, the oxidation of metal ions and precipitation of metal hydroxides. Cyanate may hydrolyze to some extent to form ammonia and bicarbonate. The ammonia, in turn, may form chloramines or be further oxidized to nitrogen.

A knowledge of the chemistry of the solution to be treated enables an estimate to be made of its chlorine demand. According to the stoichiometry of the main reactions, chlorine consumption can almost entirely be assigned to weak-acid dissociable cyanide (CN_W) in a ratio of 2.7 parts chlorine to 1 part CN_W, and thiocyanate (CNS) in a ratio of 4.9 parts chlorine to 1 part CNS. The chlorine demand can also be determined by titrating solution samples with chlorine or hypochlorite, while monitoring the redox potential of the solution. The dosage of chlorinating agent at which the redox suddenly rises (called "saturation") corresponds with the chlorine demand. If analyses of the chlorinated sample for total chlorine residual (TCR) are obtained during preparation of redox curves, an approximately linear relationship is obtained between TCR and chlorine dosage, beyond the saturation point.

3 METHODS

The program objectives were achieved by collection and interpretation of operating data and field measurements such as pH, redox, chlorine residual and flowrates together with analysis of samples by a commerical laboratory (CAN TEST LTD.) for total cyanide, weak acid dissociable cyanide, cyanate, thiocyanate, dissolved and total metals, and several other parameters. Attention was focussed on the cyanide bearing waste streams and final effluents.

Sampling and analysis methods are summarized below:

3.1 Total Cyanide (CN_T) and Weak Acid Dissociable Cyanide (CN_W)

Because of the reported adsorption of cyanide by solids(2), all samples collected for CN_T, CN_W, CNS and CNO were first filtered on a glass-fibre filter; the pH was then raised to 12 with NaOH and the sample dechlorinated, if necessary, with sodium arsenite ($NaAsO_2$). The $NaAsO_2$ was added until the total chlorine residual (TCR) of the sample was below detection. A heavy precipitate which formed upon $NaAsO_2$ and NaOH addition was not removed prior to analysis, except during special quality assurance checks.

The analytical procedure for CN_T is a modification of the standard acid reflux/distillation using hydrochloric acid and hydroxylamine hydrochloride, followed by colourimetric determination of CN(2). The method for CN_W is the same except that the reflux/distillation is carried out at pH 4.5 using an acetic acid-sodium acetate buffered solution, with zinc acetate to prevent decomposition of iron-cyanide (2).

3.2 Thiocyanate (CNS)

The sample preparation is the same as described for CN_T and CN_W. Thiocyanate was determined colourimetrically using ferric nitrate (1).

3.3 Cyanate (CNO)

The sample preparation is the same as described for CN_T and CN_W. Cyanate was determined by conversion to ammonia which was then measured by ammonia selective electrode (1).

3.4 Dissolved and Total Metals

Samples for analysis of dissolved metals were field-filtered on a 0.45 micron membrane filter and acidified with nitric acid. Total metals samples were not filtered. Problems were occasionally encountered with precipitates which formed upon acidification, and in such cases the analytical laboratory was then required to further digest the samples before metal analysis. Analysis was mainly by plasma spectrograph, but sometimes direct atomic absorption was used for cobalt, and hydride generation atomic absorption used for arsenic (1).

3.5 Field Analysis

Field analyses were performed for pH, redox, temperature, total chlorine residual (TCR) and free chlorine residual (FCR).

All redox measurements were made with respect to the saturated calomel electrode (SCE).

Total chlorine residual was measured by titrating a sample aliquot plus potassium iodide and acetic acid, with sodium thiosulfate using starch as endpoint indicator - i.e. Iodometric Method I (1).

Starch/iodide test paper was used as an indicator of the presence of free chlorine residual (FCR), although the method is not actually specific to FCR. During the testwork at Mine C, a DPD colourimetric test kit was used to determine FCR.

4 PROCESS DESCRIPTION

4.1 Mine A

The process used at Mine A follows the basic circuit shown on Fig. 1. The ore is ground and leached directly and subjected to conventional gold recovery techniques. Tailings consisting of leached and washed filter residue plus treated barren bleed (batch discharge) are conveyed to a tailings pond. Pond supernatant is periodically pumped to a secondary pond for natural degradation and exfiltration.

A batch alkaline chlorination process (Fig. 2) is utilized for treatment of barren bleed solution, with gaseous chlorine supplied from 900 kg (1 ton) cylinders. Dissolution of chlorine occurs in an eductor supplied with recirculated treated barren from the tank. Control of pH is maintained by lime slurry addition. Instrumentation consists only of pH and redox sensors and all controls are manual. Treatment of three batches per day generally is in balance with the need to release barren bleed as dictated by water balance. Each batch takes 6 - 8 hours at the maximum chlorination rate, given the throughput of the chlorinator. A rise in redox signals the completion of reaction to the operator, who then confirms it by checking for the presence of chlorine residual in the tank contents using starch/iodide test paper; the batch is then dumped and a new batch is commenced.

4.2 Mine B

The milling operation of Mine B also follows the simple circuit configuration of Fig. 1. The tailings and barren solution contain higher levels of cyanide than Mine A for two reasons:

a) the cyanide consumption is higher due to the high ore silver content, which results in more concentrated cyanide solutions,

b) use of a belt filter for secondary filtration, which has experienced poor washing efficiency and, in addition, required a belt-cleaning spray cycle which introduces an additional cyanide-laden effluent to the waste.

NOTE

ORP = REDOX

FIGURE 2 - ALKALINE CHLORINATION PLANT - MINE A

The tailings pond supernatant exfiltrates. No secondary pond is provided.

The alkaline chlorination circuits are also different. Mine B utilizes a continuous treatment system, feeding solid calcium hypochlorite (HTH) to the first of two tanks in series (Fig. 3). Redox and pH sensors are immersed in the first tank and connected to indicator/recorders. HTH is fed into the system at a rate which is known to result in the presence of a chlorine residual at the outlet, and also on the basis of long-term trends in the level of cyanide in the tailings pond. Barren bleed, lime, and HTH feed rates are controlled manually. The final effluent discharged to the tailings pond consists of leached and washed filter residue, treated barren bleed and miscellaneous streams.

4.3 Mine C

The Mine C mill and treatment systems are the most complex of the three operations studied. The feed to the leaching circuit consists of a sulfide concentrate prepared from the ore by primary flotation. After leaching and filtering, the residue is re-floated to recover graphite which is then re-leached to recover gold. Almost all process water needs are met by reclaiming water from the tailings pond. Barren bleed is treated in a primary alkaline chlorination plant prior to joining the tailings. A secondary alkaline chlorination plant is employed to treat a portion of pond reclaim water which must be discharged from the system in order to maintain water balance. The leaching of gold from a pyrrhotite concentrate gives rise to high iron and thiocyanate levels in mill solutions and effluents. In an effort to resolve metallurgical and environmental problems the mill and effluent treatment systems have been subject to almost continuous modification prior to, during, and after the testwork period.

Primary alkaline chlorination of barren bleed is carried out continuously in a disused leaching tank which provides about 8 hours of detention time (Fig. 4). Gaseous chlorine is supplied through an

NOTE

FIGURE 3 - ALKALINE CHLORINATION PLANT - MINE B

LEGEND

SAMPLE IDENTIFICATION IN PARENTHESES

ORP = REDOX

FIGURE 4 - MINE C - PRIMARY ALKALINE CHLORINATION

evaporator from three 900 kg (1 ton) cylinders in parallel. Control of pH is automatic, using lime slurry. Redox control was manual during the testwork period but is now automatic.

The secondary treatment plant (Fig. 5) provides continuous chlorination, dechlorination, filtration and pH adjustment of pond reclaim water prior to release to a stream. Automatic controls are gradually being installed although most functions were manual at the time of the testwork. Gaseous chlorine is supplied from 900 kg (1 ton) cylinders (now by way of an evaporator). A feeder supplies dry sodium sulfite for dechlorination. A pressurized pre-coat disc filter with backwash capability removes suspended solids, and final pH reduction is accomplished with hydrochloric acid. Measurement of redox provides a control signal for chlorination. Mill personnel indicated their intention to also utilize redox for control of dechlorination, subsequent to the testwork period. The detention time in the chlorination tank varies depending on the influent flowrate, but averages 45 minutes.

FIGURE 5 - MINE C - SECONDARY ALKALINE CHLORINATION

5 RESULTS - PRIMARY ALKALINE CHLORINATION

A summary of the results obtained, including percent removal, for primary alkaline chlorination is shown in Table 1. The quality of the barren being treated varied considerably between the three mines. The barren solution at Mine A contained the lowest levels of CN_T, CN_W and CNS and, consequently, had the lowest titration chlorine demand (3.2 g/L). Mine B barren solution had the highest strength solution in terms of CN_W and, coupled with a high CNS, displayed an elevated chlorine demand (9.2 g/L); however, diss. Fe was the lowest at Mine B. At Mine C, both CN_W and CNS were high, resulting in the highest chlorine demand of the three mines (12.5 g/L).

Removal of CN_T during alkaline chlorination was inversely related to iron levels, and mean removal varied between 83 and 99.6%. Percent removals were not determined for CN_{Fe} because of the poor confidence in these values, obtained by subtraction of CN_W from CN_T. However, the low removal of iron (max. 15%) for Mines A and B is consistent with the belief that alkaline chlorination is not effective in destroying iron-cyanide complexes; the higher apparent removal of iron at Mine C is due mainly to dilution from reclaim water added to the system along with barren.

Based on mean values, removal of CN_W was 99.8% or greater in all cases, corresponding with residual levels of 0.5 - 1.0 mg/L in the treated barren. Dissolved zinc and copper were 95 - 99.6% removed.

6 RESULTS - SECONDARY ALKALINE CHLORINATION

Table 2 displays a summary of test results for the secondary alkaline chlorination plant, which only existed at Mine C. Because of the low strength of the pond reclaim water being treated, the chlorine demand was also low (mean value 0.80 g/L).

As was the case for the primary plant, the final CN_{Fe} (and thus CN_T) level was dependent upon the iron concentration and found to be present in approximately the predicted weight ratio of 2.8 parts CN to 1 part Fe, which confirms its existence as the ferro- or ferricyanide complex $[Fe(CN)_6^{4-}$ or $Fe(CN)_6^{3-}]$.

Although the final mean CN_W concentration (0.30 mg/L) was lower than that obtained for any of the primary plants, the percent removal was only 97% due to the lower initial concentration.

An apparent 27% removal of iron is believed to be partially due to known (6%) dilution from fresh water added with HCl for pH adjustment but otherwise the result is inconsistent with the CN_{Fe} data (which actually showed a concentration increase, or a negative removal). Removal of Cu averaged 98.5% and zinc was below detection in the effluent. Treatment appears to have been somewhat effective in removal of ammonia (70%) although known sample preservation problems suggest caution with respect to this conclusion.

Table 2

Notes:

(1) Data for reclaim water pertains to Campaigns 1, 2 and 3.
(2) Data for treated effluent pertains to Campaign 3 only.
(3) Mean % removal calculated on basis of influent and effluent for Campaign 3.
(4) a CN_{Fe} concentration increase was obtained - removal deemed to be 0%.

7 RESULTS - OTHER EFFLUENTS

Because a gold milling operation, its tailings discharge, and effluent treatment plants are interrelated portions of a total system, it is relevant to consider the contaminant levels of other effluents.

The data in Table 3 illustrate that the discharges to the tailings ponds of all three mines contained significant levels of all relevant chemical parameters, in spite of treatment of barren bleed to low levels by alkaline chlorination. Monitoring data show that the additional contaminants mainly originate with leach residues discharged from the filters. A specific case of a sump discharge which contained water from the spray cleaning of a belt filter cloth was another major source at Mine B. Total chlorine residual was measurable in the tailings discharge, originating from the treated barren.

The quality of the tailings pond supernatant (Table 4), for most parameters, was superior to the tailings discharged, and likely reflects the effect of natural processes. Sampling of pond supernatants at Mines A and B took place in the late spring or summer; compared with the tailings discharged, lower Fe, CN_T and CN_{Fe} levels in pond supernatant are indicative of the breakdown of iron-cyanide complexes. By comparison Mine C was sampled during the winter when ice cover and cold would prevent natural breakdown, and only a small difference was noted between tailings and pond supernatant (reclaim) concentrations.

The use of a secondary pond for final effluent polishing and exfiltration is unique to Mine A. Results, presented in Table 5, demonstrate the effectiveness of the natural treatment of effluent in a shallow pond, isolated from the influence of new tailings input. In this case, essentially all parameters were reduced in comparison to the tailings pond supernatant.

8 QUALITY ASSURANCE

A quality assurance (QA) program was integrated into the testwork. It consisted of the routine preparation of unspiked and spiked replicate samples, and special sample preparations and analyses where problems were identified. The results of this program are presented in a separate volume.

The program demonstrated the difficulty of obtaining reliable analyses of total and weak acid dissociable cyanide. Selected QA data which are believed to represent most typically the statistics pertaining to each of the sample types are shown in Table 6.

In this table, data which were grossly erroneous, pertained to unsuitable spike levels, resulted from double-filtered samples, or to samples known to have been excessively exposed to light have been excluded.

It was concluded from the QA program that:

(1) Precision (relative standard deviation) and accuracy (spike recovery) both generally improved at higher CN_T and CN_W concentrations. At the levels encountered, both precision and accuracy were generally better for CN_T than for CN_W.

(2) CN_W, and to a lesser extent CN_T, are affected by exposure to light. Consistent differences were found during one QA series between otherwise identical replicate samples known to have been shipped in translucent containers and those shipped inside coolers:

Shipped in Coolers		vs.	Shipped in Translucent Containers	
CN_T	CN_W		CN_T	CN_W
48.5	0.11		51.5	4.26
44.0	0.17		45.7	4.01
5.27	5.10		5.77	5.29
1.49	1.37		2.08	1.40
258	0.40		260	3.39
260	0.55		252	6.79

In these examples, the samples having the highest CN_T concentrations were observed to release the most CN_W.

In further support of this theory, a sample spiked with 25 mg/L CN_T as $K_3Fe(CN)_6$ was found to release 17 mg/L CN_W over a period of 36 hours, if the sample was exposed to normal daylight.

These results demonstrate the need to isolate samples from the light during sample preparation, shipping, storage and analysis.

(3) Long sample storage times (up to 6 weeks) prior to analysis were believed to be a factor which contributed to erratic CN_T and CN_W results during the QA program. However, the effect of sample storage time could not be isolated from the effect of variable sample exposure to light as laboratory records do not provide this information.

(4) A series of tests which was carried out to evaluate the effect of final filtering of dechlorinated samples (see Section 3.1) indicated that the precision and accuracy of CN_T and CN_W analyses were not improved in any consistent way by final filtration. At a low level of CN_T (5 mg/L) the loss

Table 6

Quality Assurance Data

		CN_T			CN_W		
Mine	Type	Level (mg/L)	Precision S'(%)	Spike Recovery (%)	Level (mg/L)	Precision S'(%)	Spike Recovery (%)
A	Barren	230	-	101 - 110	212	-	108 - 114
B	Barren	1410	-	98 - 101	1325	-	98 - 100

B	Tailings Supernatant	17.4	3.8	94 - 97	14.8	10	101 - 108
C	Tailings Supernatant	25.6	6.2	83 - 96	13.5	2.6	86 - 96
A	Pond No.2	0.41	50	68 - 130	0.21	91	25 - 185

due to final filtration was substantial (up to 75% recorded). The results were inconsistent with respect to CN_W. Due to the loss of CN_T, final filtration is not recommended.

On this basis, it might be suspected that lack of care in thoroughly shaking the sample bottle prior to obtaining the aliquot for analysis might considerably affect the CN_T results.

(5) An evaluation of the effect of variable amounts of sodium arsenite used for sample dechlorination within the range of one-to-two-times the stoichiometric requirement for dechlorination, was inconclusive. The larger dosage appeared to decrease the CN_T concentration and increase the CN_W concentration. However, precision and accuracy were not affected in any consistent way. Further testwork is required over a greater range of sodium arsenite additions.

9 CONCLUSIONS

1. Treatment of gold mill barren solution (primary process) by alkaline chlorination was found to be capable of removing >99% of weak acid dissociable cyanide from influents having a wide variation in composition. Residual CN_W concentrations were:

	Mean (mg/L)	Std.Dev. (mg/L)
Mine A	0.49	0.55
Mine B	0.69	1.1
Mine C	0.95	1.4

2. Alkaline chlorination of tailings pond reclaim (secondary process), practiced only at Mine C, achieved 97% removal of weak-acid dissociable cyanide, producing a final effluent containing a mean CN_W of 0.30 mg/L with a standard deviation of 0.39 mg/L.

3. Primary and secondary alkaline chlorination were able to achieve up to an apparent 47% dissolved iron removal only where considerable dilution of influent streams existed; calculation on a mass basis gave a removal close to 0%. In other cases, the iron removal was, at most, 27%.

4. Final values of CN_{Fe} (i.e. CN_T - CN_W) in treated effluents were dependent upon dissolved iron levels; the ratio of CN:Fe was approximately 2.8:1, which is consistent with the stoichiometry of ferro- and ferri- cyanide complexes. Because of the low CN_W concentrations in treated effluents, the final CN_T and CN_{Fe} levels were very similar, and thus it can be concluded that alkaline chlorination is not capable of treating effluents containing high iron levels, to low CN_T concentrations.

5. Removal of dissolved copper and zinc exceeded 97% and 95%, respectively. Residual concentrations were:

	diss. Cu (mg/L)		diss. Zn (mg/L)	
	mean	std.dev.	mean	std.dev.
Mine A (Primary)	0.33	0.40	1.4	0.93
Mine B (Primary)	5.0	2.8	3.9	1.1
Mine C (Primary)	0.38	0.70	5.8	3.1
Mine C (Secondary)	0.12	0.16	<0.015	-

6. Both chlorine residuals and ammonia were found to be present in effluents treated by alkaline chlorination. Ammonia was apparently reduced by alkaline chlorination and subsequent processes in use at Mine C for treating tailings pond reclaim water.

7. Only at Mine B was any evidence found for an optimum redox potential (above saturation) which maximized the removal of cyanide and dissolved metals. However, this was not deemed to be a practical operating value, because of the steepness of the curve at this redox; in other cases the results appeared to be unaffected by the amount of excess chlorine present (as reflected by redox).

8. Total chlorine residual (TCR) concentrations in treated effluents were a reflection of any excess used during treatment. The continuous process used at Mine C produced the lowest TCR (190 mg/L, mean) in treated effluent and the continuous process at Mine B which intentionally used excess calcium hypochlorite resulted in the highest TCR (2800 mg/L, mean). However, although it was evident that downstream reactions are effective in reducing TCR levels considerably, TCR may be detectable in tailings pond supernatant, as was the case at Mine B.

2518 9. Both batch and continuous systems were found to be suitable for alkaline chlorination of gold mill effluents, with little

evidence to recommend one system over the other from the viewpoint of effluent quality. The batch system has the advantages of simplicity and more precise control of final conditions; it would therefore appear to be most economical in usage of chlorine. The continuous process requires less operator attention, which should then be supplemented with more sophisticated instrumentation (i.e. automatic control of redox). If automatic control of redox is not employed, the system must generally be operated with a surplus of chlorine in order to ensure complete oxidation under varying influent conditions, at the expense of higher chlorine consumption.

10. The final redox (in the case of batch systems) or the control redox (in the case of continuous systems) was not generally found to be critical to effluent quality provided that a chlorine residual is present in the treated effluent (exception noted in 7 above). The preparation of redox titration curves provides relevant information on the redox response to increasing chlorine dosages, but actual redox control targets are better determined by recording of corresponding redox and chlorine residuals in full-scale operating systems.

11. Carbon balances prepared for primary and secondary alkaline chlorination plants consistently showed an unaccounted loss of carbon in the treated effluents, i.e. the cyanate level was never high enough to account for the destruction of oxidizable species. There is insufficient data to indicate whether this unaccounted loss is due to conversion of cyanate to ammonia (or nitrogen) and bicarbonate, or to analytical problems.

12. Washed filter residues were determined to be the largest contributors of cyanide to tailings ponds. Additional sources were flotation tailings and other effluents containing pond reclaim water, and belt filter cleaning spray waters, in specific instances.

13. Although not within the scope of the study, there was some evidence, on the basis of total cyanide, weak-acid dissociable cyanide and dissolved iron relationships in discharges and pond supernatants to suggest the natural degradation of iron cyanides, under summer/fall conditions. No evidence was found for this phenomenon during winter sampling.

14. A secondary alkaline chlorination plant treating tailings pond supernatant appears to be at least a partial answer to the problem of untreated cyanide-bearing effluents discharged to tailings ponds. The use of a secondary pond system for polishing of tailings pond supernatant was also demonstrated to have a positive effect upon effluent quality.

15. Problems were encountered with the analyses of total and weak-acid dissociable cyanide, cyanate, thiocyanate, and ammonia. Isolation of samples from the light prior to analysis appears to be a critical factor, particularly with weak-acid dissociable cyanide.

10 RECOMMENDATIONS

(1) Ammonia, free chlorine residual, and combined chlorine residual are products of the chemical reactions in alkaline chlorination of gold mill effluents; the presence of these constituents in addition to cyanide and dissolved metals should be considered during design of future treatment systems and monitoring programs.

(2) Future operations should consider the following measures to minimize cyanide discharges to the environment:

- improved washing of tailings solids
- routing of all contaminated streams not containing solids, to alkaline chlorination
- alkaline chlorination treatment of tailings pond supernatant in addition to, or in place of, barren bleed
- the use of secondary treatment ponds for final effluent polishing
- if removal of iron cyanide is required in order to meet quality obectives for total cyanide, then an alternative process to alkaline chlorination should be considered.

(3) The various design recommendations for alkaline chlorination plants may be summarized as follows:

- properly designed and installed, both batch and continuous systems have advantages, and should be considered for use; no significant effluent quality advantages can be ascribed to one system or the other.
- the importance of pH control, in order to ensure the completion of reactions and to prevent toxic gas release, suggests that pH control be automatic for both batch and continuous systems. Audible alarms are required to warn of low pH conditions.
- whereas none of the systems studied employed redox-based automatic chlorine control (at the time of the testwork)

balancing of chlorine demand/supply. The use of automatic control of chlorine based on redox is therefore recommended for continuous systems.

- automatic control of chlorine supply in a batch system would not be appropriate, except possibly for chlorine supply shut-off in response to a minimum pH condition or batch completion. However, the one batch system observed was found to function easily with manual controls, and therefore automatic control is not recommended.
- control valves and other equipment which may have to be serviced during system operation, should be installed in such a location that exposure to toxic gases produced during the chlorination reaction, is avoided.
- reaction tanks should be covered and adequate ventilation provided.
- the need for frequent inspection, calibration, and cleaning of pH and redox sensors, suggests that they be easily accessible.
- proper feeding and metering equipment for reagents is imperative. Dry feeders should be designed to deliver, without dusting or plugging, the material being fed. They should be capable of fast, repeatable rate adjustment and be easily calibrated.
- of the oxidants studied, gaseous chlorine or liquid chlorine plus evaporators (for chlorine consumption exceeding 900 kg/d) supplied from cylinders constitutes the most convenient form.
- dissolution in water using an eductor is the conventional means of introducing gaseous chlorine into the effluent. Fresh water economies were successfully gained in two cases by use in the eductor of recycled, partially-treated effluent, ~~for the batch system studied,~~ and by use of tailings pond reclaim water in two of the continuous systems studied. Provided the eductor is located physically close to the point of application, there appears to be no reason why such effluents cannot

be used as a carrier for chlorine. Direct sparging of chlorine was not in use, and therefore cannot be commented upon.

- suitable equipment for removal of solids must be employed if the metal hydroxides precipitated during alkaline chlorination are of concern. One possible treatment option is flocculation and settling followed by filtration.

(4) Operational recommendations are as follows:

- provision of on-site technical assistance during start-up of alkaline chlorination systems.
- provision of competent analytical services for process tune-up and routine quality control.
- routine process supervision and monitoring of operating data.
- operator education regarding process chemistry, control targets and potential hazards should be provided. The importance of maintaining pH above 10.5 during alkaline chlorination so as to prevent toxic gas release should be emphasized. These and other pertinent matters may be outlined in an Operation Manual.
- redox and pH sensors must be regularly cleaned of scale and checked for breakage. This frequency should be once/day until experiences proves otherwise.
- redox and pH indicating and control instruments require regular calibration. Procedures recommended by the manufacturer should be followed in this regard.
- redox curves should be prepared for effluents on a regular basis (say, twice per week) in order to provide guidance as to relative chlorine dosages.
- the final redox (in the case of batch systems) or operating redox (in the case of continuous systems) is not critical to system performance, provided that a chlorine residual is present in the treated effluent. Provision for checking chlorine residual by the

its use. Use of starch/iodide test paper is the simplest method but will likely result in an over-usage of chlorine due to its insensitivity at the proper pH for alkaline chlorination. The final residual chlorine levels may then be related, by experience, to redox readings which would be used on a routine basis for control purposes.

(5) Because serious problems were encountered, more work needs to be done, under controlled laboratory conditions, to evaluate sampling and analysis methods for

- total cyanide
- weak-acid dissociable cyanide
- cyanate
- thiocyanate
- ammonia

relative to gold milling effluents.

FIGURE 7. TYPICAL REDOX CURVES FOR THE INFLUENTS TO PLANTS A, B AND C

CYANIDE DETOXIFICATION BY SO_2-AIR

Cyanide has been removed from flotation pulps since the 1940's at Emperor Gold Mine, Fiji RANDOL (1982), COLBERT (date?) and at Lake Shore Mines Ltd. in Ontario BLOMFIELD et al. (1941) and WILLIAMSON et al. (1947) to improve flotation performance. In these cases copper was present in the pulps.

Since 1982 INCO Ltd. have been marketing, demonstrating and expounding on the merits of an SO_2-Air copper catalyzed cyanide destruction process which has been installed in at least four small gold mining operations to date and tested successfully on a host of other pulps. SO_2-Air when compared with alkaline chlorination purely on technical ground appears to offer several advantages.

SO_2-Air Removal of					
CNS^-	Total Cyanide CN_T	Available Cyanide CN_s	Ammonia	Metals	Suitable for Slurry Treatment
No	Yes	Yes	No	Yes	Yes

MUDDER & WHITLOCK (1984) dismissed the SO_2-Air process out of hand because "estimates of chemical usage rendered this process cost prohibitive for this application (Homestake, Lead, SD.)" The basis for MUDDER & WHITLOCK's cost rejection has not been elaborated on to date. Certainly, however, SO_2-Air does not remove CNS^- or NH_3 and it also does not reach the extremely low levels of CN_T required to meet the Homestake permit.

CHEMISTRY OF SO_2-AIR CYANIDE REMOVAL

The chemistry of SO_2-Air removal of cyanide is described by DEVUYST et al. (1984) and DEVUYST et al. (1982) which are inserted below. The main features are:

$$CN_T + SO_2 + O_2 + H_2O = CNO + H_2SO_4 \text{ (fast)}$$

$$SCN^- + 4SO_2 + 4O_2 + 5H_2O = CNO^- + 5H_2SO_4 \text{ (very slow)}$$

$$2Me(CN)_n + (2x-6)SO_2 + (2x-6)O_2 + Fe + (2x-6)H_2O = Me_2Fe(CN)_6yH_2O + (2x-6)CNO + (2x-6)H_2SO_4$$

(Me=Cu,Ni,Zn)

The reactions are catalyzed by dissolved Cu which is essential to achieve low CN_T results. Also the reaction is very pH dependent and works best between pH 8.5 - 9.5. The process has commercial potential for removal of cyanide, complexed cyanide and metals including iron, but not ammonia or thiocyanate.

RESULTS OF SO_2-AIR CYANIDE REMOVAL

The results on experimental and commercial scale installations are set out clearly in the above two papers by DEVUYST et al. In general CN_T can be reduced to 0.1-0.3 mg/l in solutions and slurries and DEVUYST (1984b) indicates that copper levels of below 0.50 mg/l can be achieved in a properly designed plant.

In the data presented by DEVUYST et al. (1984) for Carolin Mines' Ladner Creek tailings it is noted that Table IV reports copper values of 5-15 ppm in the treated barren bleed and 0.5-5 mg Cu/l in the final tailings pond. These results require some explanation as they may not properly reflect the ability of the process to remove copper.

In this case some copper is left in the treated barren bleed deliberately to provide adequate catalysis in the next step where treated barren bleed and tailings are combined for further SO_2-Air treatment.

At Carolin Mines the SO_2-Air process was retrofitted in an alkaline-chlorination system and it was not ideal for the job. Consequently because the existing equipment was not ideal the SO_2-Air process was not optimised and final results of 0.5-5 mg/l Cu were obtained. With appropriate tanks designed from scratch DEVUYST (1984b) has indicated that 0.50 mg Cu/l can be achieved in this pulp.

Achieving very low metal and CN_T levels in liquid effluents requires that the reaction be carried out in a two step process settling out the $Me_2Fe(CN)_6.nH_2O$ (Me=Cu,Ni,Zn) precipitates between reactor 1 and reactor 2.

OPERATING COSTS FOR SO_2-AIR CYANIDE REMOVAL

DEVUYST et al. (1984) gave the following theoretical reagent requirements for a gold mill effluent (barren + tails) containing, for example, in mg/l: 250 CN_T, 250 SCN^- and 100 $S_2O_3^=$:

Species	Reagent g/gCN_T	
	$Na_2S_2O_5$	Lime
CN^-	3.73	1.42
SCN^-	0.67	0.38
S_2O_3	0.17	1.67
	4.57	3.47

Reagents for SCN^- and $S_2O_3^=$ are based on average oxidation of 10% of SCN^- and complete oxidation of S_2O_3 to S_4O_6. Using empirical reagent efficiencies of 90% for $Na_2S_2O_5$ (10% oxidized by air) and 75% for lime (25% unreacted), the reagent requirements for the above effluent are 5.08g $Na_2S_2O_5$ and 2.23 lime per gram CN_T oxidized.

Based on FOB Vancouver prices reported by DEVUYST et al. (1984) the cost of the process would be as follows:

Reagent	Price ($/mt)
$Na_2S_2O_5$	550
Lime	180
$CuSO_4.5H_2O$	1320

Assuming the addition of 25 mg/l Cu^{++}, the cost of treating the hypothetical effluent is C$0.95/m³.

For a typical gold mill treating 1,000 mt of ore per day at 2 lbs NaCN/ton the cost per metric ton milled is $1.90, or a yearly cost of $693,000 for reagents.

DEVUYST et al. (1984) find that at a chlorine cost of C$725/mt the reagent costs for the same waste treated by alkaline chlorination would be C$2.72/m³ or C$5.44/mt for a yearly reagent cost of C$1,980,000.

	Cost of Reagents per m³ pulp*	Cost of Reagents per t ore	Annual Costs for 1000 tpd
SO_2-Air	C$0.95	C$1.00	C$693,000
Alkaline chlorination	C$2.72	C$5.44	C$1,980,000

* (250 mg/l CN_T, 250 mg/l SCN^-, 100 mg/l $S_2O_3^=$)

ADVANTAGES AND DISADVANTAGES OF SO_2-AIR CYANIDE REMOVAL

Advantages

1) Process has been tested on numerous pulps and effluents with success, and successfully demonstrated on a commercial scale.

2) Most feed streams are already alkaline.

3) Reactions with CN_T are complete and fairly rapid.

4) SO_2 may be available as roaster gas, if not it is readily available in cylinders or in solid form as sodium sulfite Na_2SO_3, or sodium bisulfite $NaHSO_3$ or sodium metabisulfite $Na_2S_2O_5$.

5) Toxic metals are removed.

6) The process is suitable as a batch or continuous process.

7) Since SCN^- is virtually not affected, SO_2 reagent consumption is less than Cl_2 consumption which attacks SCN^-.

8) SO_2-Air removes ferrocyanides and hence achieves a much lower CN_T if iron is present in pulps or solutions than alkaline chlorination.

9) Capital outlay is relatively small.

10) The process works very well on pulps as well as solutions.

11) The SO_2 process can be retrofitted into many alkaline chlorination systems.

12) Good fail safe control.

13) SO_2-Air process is claimed to make a more comfortable work environment than alkaline chlorination if installed indoors.

14) The effluent after treatment is non-toxic, i.e., no residual Cl_2.

15) Based on comparisons of cost by INCO Ltd. the reagent consumption for SO_2-Air is much lower than alkaline chlorination for a typical gold effluent. See DEVUYST (1984).

16) Experienced technical help is available from INCO Ltd.

DISADVANTAGES OF SO_2-AIR

1) SO_2-Air does not remove ammonia or thiocyanate under normal conditions.

2) The process does not recover cyanide.

3) Metal values are not recovered except as a precipitate sludge.

4) Royalty payments may be high (if they have to be paid).

5) The toxicity of SO_2-Air treated effluents has not yet been firmly established. There is some concern about long term toxicity of CNS^- on fish, for example.

THE INCO ROLE

Various levels of royalty payments have been referred to for INCO's SO_2-Air process. A royalty of 0.75% of the gold produced by the facility using the INCO SO_2-Air process with no front end payments has been one reference. Additional charges would apply if INCO Tech Ltd. were to test the pulp, design, install and/or start up and optimize a treatment facility.

INCO Tech Ltd. have made a very significant contribution in demonstrating and optimizing the SO_2-Air process for cyanide destruction. There can be no question that the experience and knowhow of INCO Tech Ltd. technical staff in making SO_2-Air work would be valuable in the plant design or startup phase.

It is expected that there will be several more SO_2-Air cyanide removal installations to treat both pulps and solution over the next few years.

INDUSTRIAL APPLICATION OF THE INCO SO_2-AIR CYANIDE REMOVAL PROCESS

E.A. Devuyst, B.R. Conard and W. Hudson
Group Leader, Section Head, and Chief Systems Engineer
Inco, Ltd.
Mississauga, Ontario, Canada

ABSTRACT

The Inco process for continuous cyanide removal from industrial waste effluents was recently invented by G.J. Borbely, et.al. The process uses SO_2-air mixtures as an oxidant and lime for pH control and requires copper in solution as a catalyst. Iron cyanide is removed as a sparingly soluble metal ferrocyanide and other metals are removed as hydroxides. The process has been successfully tested in the laboratory on a wide variety of industrial effluents, both liquors and slurries, typically achieving less than 1 mg/L CN_T and as low as 0.05 mg/L CN_T.

The purpose of the present paper is to discuss results achieved during industrial application of this new technology. In early 1982, pilot plant tests were carried out at Campbell Red Lake Mines on barren solution with good agreement with laboratory results with respect to reagent consumptions, retention time requirements and final effluent quality achievable.

The process has been implemented at three gold mills in British Columbia that had been practicing alkaline chlorination without being able to meet effluent discharge regulations.

The first full commercial operation was at Scottie Gold Mines in October, 1982. Reactors already available on site, modified for air sparging, are being used. Barren solution and tailings slurry are treated separately with treated barren solution joining the untreated tailings slurry. During 1983, the total Scottie mill effluent discharge typically contained (in ppm): CN_T 0.2, Cu 0.2, Fe <0.03 and Zn <0.2.

The process was implemented in October, 1983, at Carolin and Du Pont of Canada Exploration's Baker mine in British Columbia. At Carolin barren solution is treated in a single existing reactor modified for air sparging and the total tailings are treated in another type of reactor. Promising results were obtained in the early stages operation with total tailings discharge analyzing CN_T 0.3-15 mg/L. At Baker, total tailings slurry was treated in two existing reactors in series, also modified for air sparging, and CN_T as low as 0.1 mg/L was achieved.

The McBean gold operation in Ontario, due to start up in 1984, is expected to use the process to treat barren solution. Also, the process has been successfully tested for treatment of various cyanide containing effluents and rinsewaters from a major electroplating shop in Ontario.

The form of SO_2 reagent used in the commercial operations is selected based on location, availability and reagent cost. At Campbell Red Lake, liquid SO_2 and roaster gases were successfully used in pilot plant treatment of barren solution.

Source: DEVUYST et al (1984)

In the B.C. locations, sodium sulfite and/or metabisulfite are currently the preferred SO_2 reagents. At McBean's gold operation the use of sodium metabisulfite is planned. The use of sulfurous acid, using SO_2 from a sulfur burner, is also possible and would be advantageous for large operations.

INTRODUCTION

The Inco process for continuous cyanide removal from industrial waste effluents was recently invented by G.J. Borbely, et.al. (1). The process is based on the use of SO_2 (gas or sulfite salt or solution) in combination with air as an oxidant and lime for pH control. Copper in solution is essential as a catalyst for cyanide oxidation. The importance of the Inco process is based on the fact that it has significant advantages over other commercial or patented processes in the completeness of cyanide removal (iron cyanide is removed), operational simplicity, better safety, and lower reagent requirements and costs.

Cyanide removal technologies, which have been reported for gold and silver mill effluents include the Prussian Blue process (2), the Cominco iron sulfide process (3), acidification - volatilization - reneutralization (4), biodegradation (5), ion-exchange (6), electro-chemical oxidation (7), the Dupont-Kastone H_2O_2 process (8), ozonation (9) and alkaline chlorination (10).

These processes cannot be judged on common criteria. Some processes, such as acidification - volatilization - reneutralization, have the objective of recovering cyanide for recycle and therefore may be cost effective if such recovery is imperative. Other processes, such as electrochemical oxidation, may be able to recover base metals as a cathodic deposit, which may be significant in the electroplating industry, or may be able to partially convert effluent SCN^- to CN^- for recycle (11). The prevalent operational philosophy at gold and silver mills, however, is to treat barren solution bleed or tailings water without concern for base metal recovery or cyanide recycle. Toward this end it is clear that successful processes must be highly reliable as far as environmental impact is concerned, and must be safe, efficient and economical to use.

Until 1982, the most acceptable process for cyanide effluent treatment was alkaline chlorination. However, it has serious shortcomings. First, safety is a concern, not only because of handling Cl_2, but also because CNCl, a very toxic gas, is known to form during treatment and must be hydrolyzed as quickly as possible by maintaining a pH of at least 10.5. Second, the process can be extremely reagent intensive and thereby very expensive. Particularly unfortunate in this regard is the preferential chlorination of less toxic SCN^- over the more toxic free CN^-. Chlorination of $S_2O_3^=$ also consumes considerable reagent. Moreover, Cl_2 is highly reactive with sulfidic minerals usually present in the mill tailings and this fact usually prohibits for cost reasons the removal of cyanide contained in tailing slurries. Third, strong oxidants such as Cl_2, do not remove cyanide complexed with iron. This results in treated effluents containing unacceptable concentrations of CN_T*, which, despite being strongly complexed, can be decomposed by ultraviolet radiation to release free CN at some later time, perhaps after discharge to the environment.

With the advent of the Inco SO_2/air process in 1981, economical, safe and reliable treatment of cyanide containing solutions or slurries is possible and achieves low CN_T concentrations (including Fe complexes). The purpose of this paper is to report the commercial results of this technology at three gold mills in Canada.

* CN_T = total cyanide, including free CN^-, HCN and complexes of cyanide, SCN^- is not included.

PROCESS CHEMISTRY

The SO_2/air process has been extensively described in several recent Inco publications (12-16).

The oxidation of cyanide (free and complexed with transition metals other than iron and cobalt) closely follows the stoichiometry of the following overall reaction to form CNO^-:

$$CN^- + SO_2 + O_2 + H_2O \rightarrow CNO^- + H_2SO_4 \qquad (1)$$

Based on this reaction, the SO_2 requirement is 2.47g SO_2 per g CN. The cyanide oxidation reaction is catalyzed by the presence of copper ions in solution. Often the necessary copper ion concentration is already present in the effluent to be treated. When the copper concentration is insufficient, it is usually added as a copper sulfate solution. The optimum operating pH is in the range 8 to 10. Temperature has no significant effect on the cyanide oxidation rate in the range 5 to 60°C. The preferred volume percent SO_2 (or equivalent SO_2 volume percent if a sulfite solution is used) in air is at or below 2, but SO_2 of up to 10 vol.% in air can be successfully employed.

The kinetics of oxidation of thiocyanate with SO_2/air are slow under normal process conditions and usually less than 10% of the thiocyanate is oxidized during treatment.

During cyanide oxidation, iron cyanide is removed from solution by precipitation of insoluble metal ferrocyanide compounds of the form $Me_2Fe(CN)_6$ (where, for example, Me = Cu, Zn and Ni). Excess copper, zinc and nickel are removed by precipitation of metal hydroxides at the reaction pH. Metals forming weak cyanide complexes, such as arsenic and antimony, can also be removed by oxidation - precipitation in the presence of iron.

PROCESS APPLICABILITY

Details of successful laboratory treatment of a wide variety of Canadian gold and/or silver mill effluents, both barren solutions and tailings slurries, were reported in previous publications (13-15). Miscellaneous effluents such as flotation tailings and coke oven and blast furnace scrubber waters were also successfully treated (14). To date, Inco has successfully tested over fifty effluents without failure, but treatment conditions and control strategy vary considerably. Recently Canviro Consultants has reported results on the application of the Inco SO_2/air process to a variety of Canadian gold mill barren solutions and effluents from metal finishing operations (17).

PILOT PLANT

Starting in February, 1982, piloting of the Inco SO_2/air process was carried out on barren bleed solution at a facility constructed at Campbell Red Lake Mines Ltd. (in Ontario) and was operated by Inco personnel for a total of five weeks (the last three weeks running continuously).

The circuit comprised two reactors operated in series with the option of solids removal between stages. Air or roaster gases (about 1 vol.% SO_2) were supplied to the reactors by a blower. When running without roaster gases, SO_2 (liquid) from one ton cylinders was metered into the air stream. A pH electrode in each cell was used to control lime addition to maintain the pH set-point. Monitoring the ORP was successfully used as a guide for both SO_2 and copper

catalyst addition rates. Hoods were installed over the reactors and were connected to a ventilation duct. An hydrogen cyanide monitor installed in the duct with an alarm setting at 5 ppm HCN was not triggered at any time during the campaign.

Typical results achieved in the laboratory and at Campbell Red Lake for the flowsheet shown in Figure 1 are summarized in Table I. Detailed results of the campaign are available in a separate Inco publication (15). Results show cyanide removal from 890 mg/L in the feed to <0.7 mg/L in the second stage effluent when SO_2 was supplied at >3.0 g/g CN_T. Both laboratory and pilot plant results showed the process improved when Ni/Fe-containing solids were removed between treatment stages. Roaster gases were shown to also be acceptable as an SO_2 and air source. There was generally very good agreement between pilot plant and laboratory results when operating under the same conditions.

COMMERCIAL INSTALLATIONS

Due both to the failure of alkaline chlorination plants to achieve required effluent quality and high operating costs, three gold mills have licensed the Inco SO_2/air process for their cyanide destruction. At each of these sites chlorination facilities existed. To avoid further capital expenditures, each site requested that the implementation of the SO_2/air process use the existing equipment wherever possible. Thus, none of these commercial installations may be considered the most appropriate way to carry out or control the process, but the good results achieved to date show the flexibility the process has for accommodation to various design concepts and local conditions.

Scottie Gold Mines

Scottie Gold Mines, near the town of Stewart, British Columbia, was the first licensee in October, 1982. Scottie mines a pyrrhotitic ore at 200 t/d with a grade of about 0.50 oz/t. The ore is leached with cyanide following grinding in a mill located underground. Leached tails are washed and discarded. Gold recovery from pregnant is by Zn precipitation. Barren solution bleed may average 130 m^3/d. Prior to SO_2/air at Scottie two stirred tanks in series were in use for alkaline chlorination on barren solution bleed. Washed tailings solids were discarded directly to a pond and at times contained up to 10% of the total cyanide bleed.

Two tanks previously used at the site for alkaline chlorination and a third tank that was available were equipped with air spargers and agitators. Although liquid SO_2 could have been used, the transportation problems due to the remote location of the mine and safety considerations due to Scottie's underground mill caused other forms of SO_2 to be investigated. Two solid forms of SO_2, namely, sodium sulfite (Na_2SO_3) and sodium metabisulfite ($Na_2S_2O_5$) were selected. These reagents were dissolved in water in small make-up tanks and were added at the desired rates.

A schematic of the circuit at Scottie Gold is shown in Figure 2. Barren solution bleed is treated in one reactor with Na_2SO_3 and $Na_2S_2O_5$. The addition of Na_2SO_3 is made in proportion to the total weight of CN in the barren bleed. The addition of $Na_2S_2O_5$ is only made if the pH in the reactor rises above 9. Copper sulfate solution is added to the barren bleed from a small holding tank by means of a Clarkson feeder. The treated barren is mixed together with the washed mill tails from the tailings repulper in reactor II where they are treated with Na_2SO_3 and $Na_2S_2O_5$ solutions in the presence of air. Reactor II overflows into

reactor III where the reaction is continued. Typical results achieved in the laboratory and in the plant are summarized in Table II.

The most significant fact about Scottie's effluent treatment is that during all of 1983 Scottie was able to keep the CN_T in their treated effluent below 1 mg/L on monthly averaged analyses.

Du Pont of Canada Exploration's Baker Mine

The Baker Mine, owned and operated by Du Pont of Canada Exploration, is located near Smithers, British Columbia. It is completely serviced by air. This mine operated at 100 t/d on a combined gold-silver ore graded at about 1.1 oz/t (gold equivalent). Leaching was carried out using NaCN. Filtered tailings generally had about 20% of the total cyanide bled from the system. Barren bleed and sump water accounted for the remaining 80% of the cyanide.

Prior to licensing the Inco process, Baker had treated barren bleed in two reactors in series using $Ca(OCl)_2$ and $Ca(OH)_2$ in the first reactor. The treated barren overflowed into a tailings reactor, which also received sump water. Details of this operation were reported by W.W. Muir (18). One of the concerns at the Baker mill was that the washed tailings and sump water were left untreated by chlorination and, due to their small holding pond, insufficient natural degradation was obtained.

The Inco process was licensed in October, 1983. After modifying three existing reactors for air sparging, a similar approach for effluent treatment as used at Scottie Gold was initially tested. Barren bleed solution was treated with Na_2SO_3 in the first reactor, overflowing into a second reactor where only air was added. Since the third reactor receiving the tailings solids could not be moved, the tailings solids, sump water and treated barren solution were combined in the third reactor and treated with $Na_2S_2O_5$.

Due to limited compressed air availability the system only worked at low barren bleed flows. Also, due to the excessive basicity of the tailings solids, a large excess of $Na_2S_2O_5$ was required in the third reactor simply to keep the pH in the desired range.

Based on the results of further laboratory studies an improved circuit was installed in which total tailings slurry was treated in two reactors in series with addition of $Na_2S_2O_5$ to the first reactor as shown conceptually in Figure 3. A dedicated compressor was used with the two reactors. Washing the tailings solids with barren solution instead of fresh water eliminated the need of taking a separate barren bleed, since sufficient barren bleed was obtained in the form of tailings cake moisture.

Typical results achieved in the laboratory and in the plant are summarized in Table III. Both achieved CN_T from 0.1 to 0.3 mg/L in the final slurry.

Carolin's Ladner Creek Operation

Carolin Mines' Ladner Creek mill is the most complex of the mills in which the SO_2/air process has been employed. Mill capacity is about 1300 t/d with an ore grade of about 0.1 oz/t. Flotation is used to upgrade the gold into a sulfide concentrate which is then leached with cyanide. The tails are sent to scavenger flotation cells where a graphite concentrate is further recovered.

Barren bleed is typically about 150 m^3/d. Process water is obtained by recycling tailings pond supernatant. Considerable efforts were made by Carolin to optimize effluent treatment by alkaline chlorination. In that prior work, a large agitated tank was used to treat barren bleed with chlorine and lime. Washed tailings solids, containing 5 to 10% of the cyanide bled, were discarded to the tailings pond without treatment. Pond supernatant was treated in a secondary alkaline chlorination circuit and then dechlorinated and pH adjusted prior to discharge to Ladner Creek. However, the rate of discharge from the pond was limited by the presence of iron cyanide in the pond. The iron cyanide was found to increase during the winter months and this created serious problems for Carolin during periods of spring run off.

The Inco process was licensed in October, 1983. Since more than 90% of the iron in the pond originated from the barren bleed, implementation of the Inco SO_2/air on barren solution was carried out first.

The schematic flowsheet of the Inco SO_2/air process at Carolin is shown in Figure 4. Barren bleed is treated in the same tank as was used for chlorination, but two aeration agitators were positioned on a bridge support on each side of an existing central aerator. Addition of $Na_2S_2O_5$ is in proportion to the barren flowrate and cyanide content. No copper sulfate addition is required. Lime is added on pH demand by means of a titrator-pH controller.

In the current practice, tailings solids are also treated at Carolin. This is done by adding excess $Na_2S_2O_5$ to the treated barren overflow which joins the tailings box. Some $Na_2S_2O_5$ is also added to flotation scavenger cells, which provide good aeration.

Typical laboratory and plant results achieved on treatment of barren solution are shown in Table IV. Treated barren with (in mg/L): 10 CN_T, 5-15 Cu and 0.1-0.3 Fe was obtained. These results are not as good as in the laboratory where the effluent analyzed (in mg/L): 1.4 CN_T, 1.4 Cu and 0.4 Fe, but inadequate mixing and poor air dispersion in the plant reactor are likely responsible. While this could be catastrophic for another location, achieving low cyanide in the treated barren at Carolin is not critical, since further cyanide removal can be obtained by addition of $Na_2S_2O_5$ to the treated barren overflow which joins the tailings box. Typical total tailings treatment obtained is summarized in Table IV. With no addition of excess $Na_2S_2O_5$, the typical CN_T in the total tailings discharge to the pond was 15 mg/L (with 90% of the cyanide being contributed by the tailings input). With addition of $Na_2S_2O_5$, cyanide was removed to the range 0.3 to 2 mg/L in the tailings discharge to the pond. An estimated 12 mg/L of cyanide is removed in the tailings pipe for this operation. Based on these results, $Na_2S_2O_5$ addition to the scavenger cells is now also being made to take advantage of the aeration present in these cells and hopefully to further improve CN_T in the tailings discharge.

General Comments

Reactor Selection. In the presence of sufficient copper catalyst, the rate-limiting step in the oxidation of cyanide in the SO_2/air process is determined by the rate of oxygen transfer to the solution. Therefore, reactors providing maximum air dispersion and good agitation are preferred. Flotation cells are considered to be excellent reactors for applications of this process. Flotation cells were used by Inco at Campbell Red Lake and excellent agreement was obtained between laboratory and pilot plant operation with respect to retention time, reagent requirements and effluent quality achieved. The Inco process is, however, not limited to the use of flotation cells. Simple agitated tanks, modified for air

sparging, can be considered. Such reactors, depending on size, could be fitted with flotation-type agitators for air dispersion.

In general, air dispersion efficiency per unit volume of reactor decreases with increasing reactor size and it may be preferable to use two or more smaller reactors instead of one reactor of equal total volume.

Reagent Selection. The choice of SO_2 reagent is dependent on mine location, reagent cost and process control strategy. The cheapest primary reagent for SO_2 is elemental sulfur. Conversion of the sulfur to SO_2, however, requires a sulfur burner and this may not be economically justified for small operations. Liquid SO_2 has a relatively low cost if it can be brought to the site by rail. Liquid SO_2 in one ton cylinders has a unit cost similar to solid sulfites such as Na_2SO_3 and $Na_2S_2O_5$. The use of liquid SO_2 requires a reliable lime delivery system for pH control. Sodium sulfite compounds,on the other hand, are quite soluble in water (up to 250 g/L), and are safer and more convenient reagents for both SO_2 supply and neutralization (containing equivalent or half of the base required to neutralize the acid generated).

Treatment Options. If a mine recovers gold by carbon in pulp, total tailing slurry treatment is required. The Inco SO_2/air process is quite suited for this treatment. The number of reaction tanks required, and whether in sequence or in parallel, should be determined by empirical studies.

Gold mines recovering gold by zinc cementation produce two effluents, namely, barren solution bleed and repulped tailing solids. The optimum effluent treatment scheme for such a mill is dependent on the particular mill operation, retention time available, SO_2 reagent usage, effluent composition, solids composition and process control strategy. Inco has wide experience in designing systems for these variables and should be consulted during the testing and design stages of any plant.

Process Control. Process control strategy for optimum performance and most economical use of reagents is quite site specific. Numerous options are available and have to be evaluated under laboratory conditions. Inco has a continuous bench-scale apparatus for this kind of testwork.

OPERATING COSTS

Theoretical reagent requirements for the oxidation of cyanide contained in a gold mill effluent (barren + tails) containing, for example, in (mg/L): 250 CN_T^-, 250 SCN- and 100 $S_2O_3^=$, are as shown below:

Species	Reagent(g/g CN_T) $Na_2S_2O_5$	Lime
CN^-	3.73	1.42
SCN^-	0.67	0.38
$S_2O_3^=$	0.17	1.67
	4.57	1.67

Reagents for SCN^- and $S_2O_3^=$ are based on average oxidation of 10% of SCN^- and complete oxidation of $S_2O_3^=$ to $S_4O_6^=$. Using empirical reagent efficiencies of 90% for $Na_2S_2O_5$(10% oxidized by air) and 75% for lime (25% unreacted), the reagent requirements for the above effluent are 5.08g $Na_2S_2O_5$ and 2.23g lime per gram CN_T oxidized.

Prices FOB Vancouver (all currency expressed in Cdn $) for reagents are:

Reagent	Cost ($/MT)
$Na_2S_2O_5$	550
Lime	180
$CuSO_4.5H_2O$	1320

Based on these costs and using the above reagent requirements, also taking into account an average addition of 25 mg/L of Cu^{++}, the cost of effluent treatment per m^3 is $0.95. For a typical gold mill treating 1,000 MT of ore per day at 2 lbs NaCN per MT, the cost per MT milled is $1.90. This corresponds to a yearly reagent cost of $693,500.

Alkaline chlorination, on the other hand, using an empirical reagent efficiency of 75% for both Cl_2 and lime, has reagent costs for treatment of the same effluent of $2.72/$m^3$ or $5.44/MT (Price FOB Vancouver for Cl_2 is $725/MT). The corresponding yearly reagent cost is about $1,980,000. Consequently, for this typical effluent, the savings achieved with the SO_2/air process is $1.77/$m^3$ effluent or $3.54/MT milled or $1,290,000 per year. This calculation considers a "good" case for chlorination since most tailings slurries would be more highly reactive to chlorine and would consequently have a considerably higher chlorine reagent cost. Moreover, if the SCN^- concentration is increased over 250 mg/L (used in the example), which is often found to be the case, then the chlorine consumption and cost is significantly higher, but the SO_2/air reagent cost only marginally increases due to only 10% of the SCN^- being oxidized by the latter process compared to 100% by chlorination. Finally, any iron present in the effluent cannot be removed by chlorination and therefore, despite its high cost,chlorination is unable to produce an effluent of equal quality to that produced by the lower cost SO_2/air process.

Licensing of the SO_2/air technology is handled through IncoTech, a Division of Inco, Ltd. Licensing fees are a fraction of the savings the process offers.

ACKNOWLEDGEMENTS

The authors would like to thank many Inco personnel for their discussions and assistance during the course of this work: Inventors G. Borbely, K. Schitka, V. Ettel and A. Mosoiu, who maintain an active interest; B. Tandi, who has skillfully conducted all the laboratory work reported; analytical services and advice from V. Zatka and P. Iamarino; plant operational assistance from R. Agius, B. Wilson, E. Lostracco and F. Daley, and Inco Tech assistance from D. Lowney. In addition, successful testing and implementation could not have been done without the cooperation of S. Roberts at Campbell Red Lake, Wayne Ash at Scottie, T. Law and W. Muir at Baker, and G. Robbins and R. Samuels at Carolin.

INCO TECH

2060 Flavelle Boulevard, Sheridan Park
Mississauga, Ontario L5K 1Z9

September 24, 1982

Dear Sir or Madam,

Thank you for your inquiry about the Inco SO_2/air process for cyanide removal from industrial effluents.

Enclosed please find several recent papers on this subject, the most recent one being given in September, 1982, reporting pilot plant and initial full-scale plant trials on gold mill barren and tailings slurries.

We will continue to keep you informed about the process developments as they occur. Technical questions can be addressed to:

Dr. Bruce R. Conard
Inco Ltd. Research Labs
Sheridan Park
Mississauga, Ontario. L5K 1Z9
Tel: (416) 822-3322

Licensing information should be requested from:

Mr. Donald Lowney
Manager - Administration
Inco Tech - Inco Ltd.
Mississauga, Ontario. L5K 1Z9
Tel: (416) 822-7265

Again, thank you for your interest.

Sincerely yours,

BRConard.

A UNIT OF INCO LIMITED

A NEW PROCESS FOR THE TREATMENT OF WASTEWATERS CONTAINING CYANIDE AND RELATED SPECIES

TO BE PRESENTED AT THE 21st ANNUAL
CONFERENCE OF METALLURGISTS,
TORONTO, ONTARIO
AUGUST 29-SEPT. 1, 1982

ABSTRACT

A new process for the removal of free and complexed cyanide in wastewaters has been developed by Inco laboratories using sulfur dioxide (either as gas or as sulfite solutions), air and lime. High reaction rates are obtained at room temperature at pH = 7-10 in the presence of dissolved copper, which acts as a catalyst. Cyanide in the treated effluents can be reduced to <1 mg/L CN_T, including cyanide complexed with iron.

Examples of laboratory continuous treatment of gold mill effluents, plating rinse waters and flotation liquors are given.

Pilot plant experience treating barren solution at the Campbell Red Lake operation is discussed, as well as promising results from a plant trial at Scottie Gold Mines.

INTRODUCTION

A number of important industrial processes produce waste effluents containing high levels of cyanide either as a free ion or complexed with heavy metals. Before being discharged into receiving waters such effluents need to be treated to achieve acceptably low levels of cyanide.

Various techniques for oxidizing cyanide to less toxic species using strong oxidants are reported in the literature (1-8). Other reported methods use ion-exchange(9), iron sulfide(10), ferric hydroxide(11), polysulfides(12), aeration at low pH(13) and ferrous sulfite(14). Excellent reviews of the field have also recently appeared(15,16).

Of the methods known, alkaline chlorination is the most widely used in commercial practice. This method, however, has several serious shortcomings, namely, high reagents costs due to thiocyanate being oxidized prior to cyanide, formation of highly toxic cyanogen chloride as a reaction intermediate, contamination of the effluent by chlorine, and incomplete oxidation of the cyanide complexed with the iron, which remains in solution as $Fe(CN)_6^{-3}$ and has the potential for release of free cyanide at a later time. Recently the $FeSO_4$ + sulfite process has received some attention. However, possible serious shortcomings may be relatively high reagent costs ($FeSO_4$ and Na_2SO_3 or $NaHSO_3$ and NaOH or Na_2CO_3), difficult solid-liquid separation operation(solids containing possibly ferric hydroxide), and multi-step operation(addition of sulfite and $FeSO_4$, neutralization, filtration).

Inco Limited has reported a new method for removing cyanide in solution involving SO_2/air as an oxidant and small amounts of dissolved copper as a catalyst(17). The potential advantages of the process are:

- removal of both free and complexed cyanide, especially complexed with iron, to achieve effluents containing total cyanide(CN_T) of <1 mg/L;
- very rapid kinetics at room temperature;
- low reagent consumption because thiocyanate(SCN^-) is only slowly oxidized under the preferred conditions;
- possible low reagent cost because roaster gas can be used as oxidant where available or elemental sulfur can be burned to provide SO_2.

Details of successful laboratory treatment of a wide variety of Canadian gold mill barren solutions and pulps, as well as a number of other industrial waste waters, and pilot plant treatment of barren solution at the Campbell Red Lake gold mill, were reported in three previous publications(18,19,20). The objective of the present paper is to summarize and update the data on the SO_2/air process. The process is shown to be applicable to cyanide removal from flotation tailings liquors and slurries, plating rinse waters, coke oven and blast furnace scrub waters, silver and gold milling barren solutions and slurries. Laboratory, pilot plant and plant results are presented.

PROCESS CHEMISTRY AND VARIABLES

The overall reaction for cyanide oxidation with SO_2/air is postulated to be

$$CN_T^- + SO_2 + O_2 + H_2O \rightarrow CNO^- + H_2SO_4$$

The reaction is catalyzed by copper approximately in proportion to the amount of copper present in the range 0 to 50 mg/L as shown in Figure 1. The amount of copper catalyst necessary is somewhat variable depending on the specific effluent being treated.

Figure 1
EFFECT OF COPPER

In the presence of 50 mg/L copper, the effect of varying the treatment pH in the range 6 to 11, at room temperature, is shown in Figure 2. The preferred range of pH is 9-10. Again, depending on the specific effluent being treated, or the type of sulfite-air mixture used, another operating pH may be preferred.

Studies previously reported(18,19) have shown that temperature variation in the range 4-60°C has no significant effect on the process. Sulfur dioxide concentrations between 0.5 to 10 vol.% can be used, but for optimum oxidation efficiency a range of 1-3 vol.% SO_2 in air is preferred.

The order of metal cyanide removal in the SO_2/air process is Zn>Fe>Ni>Cu. The Fe cyanide complexes are reduced to the Fe^{++} state by SO_2/air and the insoluble salts $Me_2Fe(CN)_6.xH_2O$(Me = Zn, Cu, Ni) precipitate during treatment. Following the removal of Fe in this way, the remaining Cu, Zn and Ni ultimately report to the solids as hydroxides as the cyanide is oxidized to cyanate.

The oxidation of thiocyanate according to the postulated overall reaction:

$$SCN^- + 4\ SO_2 + 4\ O_2 + 5\ H_2O \rightarrow CNO^- + 5\ H_2SO_4$$

is very slow, but SCN^- can quickly react with other species that may be present, such as $Ni(OH)_2$, to release free cyanide which, of course, is not desirable. This type of reaction can be minimized by removing the solids in an intermediate step or in some instances by operating at lower pH.

Figure 2
EFFECT OF pH

2553

LABORATORY EXPERIMENTAL PROCEDURE

Laboratory tests were carried out either batchwise in a 1 liter capacity reaction vessel or continuously using one or two 0.5-1.5 liter capacity vessels placed in series(Figure 3). Sulfur dioxide was added into each vessel as a mixture in air(0.6 - 3 vol.% SO_2). In some cases a sodium sulfite or sodium meta-bisulfite solution was used instead of SO_2. The experiments were conducted at room temperature keeping a pH 9 or in some cases 6.5 to 10, using a lime-water suspension(38 g/L lime). When feed composition dictated, copper was added as a cupric sulfate solution to the feed. The reduction-oxidation potential(Redox) versus the standard calomel electrode (S.C.E.) was monitored in each reaction vessel.

In all of the testwork carried out more reliable data was obtained from continuous processing than from batch tests. Batch tests were only conducted to scope the SO_2/air process on a particular effluent.

LABORATORY RESULTS ON INDUSTRIAL EFFLUENTS

The SO_2/air process was tested on a wide variety of industrial waste liquors and pulps which originate from the following typical operations:

(a) precious metals extraction(silver and gold milling)

(b) mineral dressing(pyrrhotite and base metal flotation)

(c) electro-plating(rinse waters)

(d) steel manufacturing(coke oven and blast furnace scrub waters)

Figure 3
LABORATORY CONTINUOUS SET UP

The above effluents contain, in addition to cyanide(free and complexed with heavy metals), variable amounts of thiocyanate, flotation agents, ammonia and organics. The principal metals present at various concentrations are copper, nickel, iron, zinc, arsenic and cadmium.

Treatment of effluents from flotation tailings

Examples of continuous treatment of flotation tailings liquors are shown in Table 1.

For liquors from pyrrhotite flotation, for example, in which synthetic stack gas(air + 0.6 vol.% SO_2 + 1 vol.% CO_2) was used, the pH in each of the two stages was kept at 6.5 instead of the preferred pH of 9, to avoid excessive lime consumption by reaction with CO_2 in the gases. A total residual cyanide(CN_T) of 0.6 mg/L was obtained with a total retention time of 7.4 minutes. None of the thiocyanate was removed at this pH. A high grade precipitate at ~20 wt.% Ni + Cu was recovered.

For liquors resulting from flotation of copper and copper-zinc ores, very low residual cyanide levels(CN_T <0.1 mg/L) were obtained by treating the effluents with SO_2/air at pH 9. The exceptionally low CN_T in this case is attributed to a low Ni and Fe content of the feed. Such effluents can be treated in one stage continuous to achieve CN_T <1 mg/L as shown in Table 1.

Examples of batch treatment of pyrrhotite tailings slurries are shown in Table 2. The tailings, containing 62% by weight solids, were reacted with SO_2/air at pH 8. No cyanide was removed in the absence of copper addition. With addition of copper at 160 mg/L(on a continuous basis as $CuSO_4$) virtually all of the cyanide was removed.

Treatment of plating rinse waters

An example of two stage continuous treatment of mixed cadmium and zinc plating rinse waters is shown in Table 1. Although the total cyanide was removed to below 0.5 mg/L in the first reaction stage, a residual copper concentration of 6 mg/L remained in solution. This copper is presumably present as a Cu^{+} complex with inorganic or organic species present in the effluent and gradually hydrolyses out of solution by oxidation of Cu^{+} to Cu^{++}. The final effluent, after standing for 36 minutes at pH 10, analyzed 0.8 mg/L Cu.

Treatment of silver mill barren solution

Results of a two stage continuous treatment of silver mill barren solution with SO_2/air at pH 9 is shown in Table 1. Very low residual CN_T of 0.04 mg/L was attained, which is typical of the results achieved in the absence of Ni and Fe. Analyses of the various streams for CNO^{-}, SCN^{-} and NH_3 indicate that most of the cyanide was oxidized to CNO^{-} with some of the CNO^{-} hydrolyzing to CO_2 and NH_3 and a very minor amount of the cyanide(less than 2% of CN_T) reporting with the residue.

Treatment of coke oven and blast furnace effluents

Unlike most other effluents, coke oven and blast furnace effluents from gas scrubbing mostly contain free cyanide and traces of iron. The effluents also contain ammonia and variable amounts of phenol.

Results of batch treatment of such effluents with SO_2/air at pH 9 are given in Table 2. Copper catalyst addition was required to achieve total cyanide removal. Only part of the phenol was removed and none of the ammonia.

Treatment of gold mill barren solutions

Results of two stage continuous cyanide removal from several gold mill barren solutions using SO_2/air are given in Table 3. These results show that:

- CN_T in the treated effluents was <.5 mg/L for effluents containing no or small amounts of nickel; the weak acid dissociable cyanide(CN_W) was in some cases below 0.1 mg/L.
- reagent consumptions were in the range 3 to 7 g SO_2 and 6 to 10 g lime per g CN_T. When Na_2SO_3 was used(effluent A), no lime was required.
- metal impurities, including As(when present), were usually removed to well below 1 mg/L. In some cases, however, 1-2 mg/L of Cu, Ni and/or Zn remained in solution at the time of sampling, even though the CN_T was below 0.1 mg/L. It would appear that hydrolysis of these metals is retarded by the presence of complexing ions in solution. These effluents always showed much lower metal concentrations when refiltered at a later time.

- very little SCN^- was oxidized, resulting in low SO_2 consumptions.
- the bulk of the cyanide was oxidized to cyanate (CNO^-) with some of the CNO^- hydrolyzing to NH_3 and CO_2. When iron was present, some of the cyanide was precipitated with iron as $Me_2Fe(CN)_6.x\ H_2O$(Me = Ni, Cu, Zn).

Total removal of cyanide from effluents containing high nickel and iron concentrations was difficult to attain(see Table 4), because of the back-reaction of precipitated solids with solution species. A substantial improvement in residual CN_T in a second treatment stage was obtained by removing the solids between stages: effluent C(Tables 3 and 4) yielded a final treated effluent with 0.3 mg/L instead of 1.2 mg/L CN_T and effluent E gave a treated solution with 0.7 mg/L instead of 6 mg/L CN_T. Copper addition was required in effluent E because of the very high Fe content of this feed.

Solids precipitated from iron containing effluents are stable towards cyanide redissolution in the pH range 4 to 9 as shown in Table 5. Treated effluents were acidified to pH 6 and 4 in the presence of the cyanide containing solids and reanalyzed after 4 and 7 days. Only acid soluble hydroxides were redissolved.

* Feed F: carbon in pulp gold extraction; 4 Vol.% SO_2 in air; sulphidic solids.
Feed E: gold cementation with Zn powder; 134 g/L Na_2SO_3 solution; sulphidic solids.
Feed H: carbon in pulp gold extraction; 1 vol.% SO_2 in air; roasted solids.

Treatment of gold mill barren slurries

Results of successful continuous cyanide removal tests from various gold mill barren slurries using SO_2/air are given in Table 6. Feeds F and H result from carbon in pulp treatments and feed G from zinc cementation treatment of pregnant solution. Feeds F and G contain sulfidic solids and feed H roasted solids, mainly hematite.

The results show that:

- the residual total cyanide in the treated effluents was in the range 0.1 to 2 mg/L and the weak acid dissociable cyanide(CN_W) in the range 0.07 to 0.8 mg/L.
- the cyanide was removed in a single stage continuously with typically ~30 minutes retention time.
- reagent consumptions were in the range 5 to 8.5g SO_2/g CN_T. Feed G was treated with sodium metabisulfite and required no base.
- the preferred treatment pH with slurries is 8. Higher pH may result in incomplete iron removal(feed H).

Slurries containing more highly reactive solids towards SO_2 and air may require more intensive treatment conditions.

Figure 4
PILOT PLANT FLOWSHEET

PILOT PLANT RESULTS

Detailed results on a five week pilot plant trial at the Campbell Red Lake gold mill were given in a previous publication(20). The pilot plant circuit comprised two 2 m^3 flotation tanks(Figure 4), and one 50 m^3 thickener.

Use of Roaster Gases

The use of roaster gases as the oxidizing reagent, instead of liquid SO_2 in air, was tested without intermediate solids removal. Excellent results were obtained, as summarized in Table 7, with the second stage effluent reporting at 1.6 mg/L CN_T. Roaster gas SO_2 strength was not measured during the test, but we calculate that it was about 0.6 vol.% SO_2.

Optimum results

Roaster gases were not used for process optimization because precise SO_2 addition rates were required. Results from both laboratory and pilot plant treatment of Campbell effluent showed the necessity of removing Ni/Fe-containing solids and minimizing CN_T in reactor 1 to achieve the lowest residual CN_T in the treated effluent. When CN_T is plotted versus redox for reactor 1(see Figure 5) using all data obtained from the pilot plant and laboratory tests, a clear CN_T minimum is found between +90 mV to +130 mV (S.C.E.). Optimum results were obtained by controlling the SO_2 addition rate to reactor 1 to maintain +110 mV redox. Under the optimum conditions, the residual CN_T achieved in the treated effluent was <0.7 mg/L and the weak acid dissociable cyanide(CN_W) was <0.2 mg/L(Table 7).

CAMPAIGN No. 4, 3, 2 & LABORATORY, REACTOR 1

PLANT RESULTS

The Inco SO_2/air cyanide removal process on both barren solution and tailings slurries is currently being tested on a plant scale at Scottie Gold in B.C. Initial results are promising. The tests on barren bleed were carried out continuously at 100-400 L/min effluent feed rate to a 6 m^3 stirred reactor using air and sodium sulfite solution as the oxidizing reagents. Typical results are shown in Table 8.

It was not possible to analyze for CN_T at the plant site, and therefore the picric acid method for cyanide analysis was used. Since the CN_P gives the free cyanide and cyanide complexed with Cu, Ni and Zn, and was measured to be <.1 mg/L in the treated effluent, the only cyanide present was due to cyanide complexed with iron. The maximum cyanide complexed with 0.2 mg/L Fe is 0.6 mg/L as $Fe(CN)_6^{3-}$ and therefore the CN_T in the treated effluent was below 0.7 mg/L.

Plant tests on tailings slurry at this site are continuing.

SUMMARY

A new and comparatively inexpensive process for removing cyanide in waste waters has been developed and successfully tested on a wide variety of effluents. Reagents required are SO_2(gas, sulfite, roaster gases), air and neutralizing agent(eg. lime) and process consumptions are low, typically ~5 lb SO_2 and 8 lb $Ca(OH)_2$ per lb CN_T in the feed. The cyanide is removed by both oxidation to cyanate and by precipitation as insoluble ferrocyanide salts.

PLANT CONTINUOUS TREATMENT OF GOLD MILL BARREN SOLUTION

Stream	pH	Analyses (mg/L) CN_p^-	Cu	Fe	Zn	SO_2 Added (g/g CN_T) (as Na_2SO_3 soln)
Feed	11.0	240	50	20	25	-
Treated Effl.	9.6	<.1	<.5	0.2	<.2	10

Feedrate: 35 US Gal/min

Retention: 170 min.

CN_p = CN by picric acid method which excludes iron complexes.

The oxidation of cyanide is catalyzed by soluble copper, which can be present in the feed or can be added to the process as Cu^{++}. Little SCN^- oxidation is experienced. Metal values in the feed report as hydroxides or as metal-ferrocyanide salts.

Excellent laboratory results have been achieved in a continuous operation using waste waters and pulps produced in gold milling, pyrrhotite and base metal flotation, plating shop rinse waters and metallurgical coke oven and blast furnace operations.

A successful five week pilot plant operation of the process was demonstrated at Campbell Red Lake on their barren solution. Roaster gases were shown to be an effective source of SO_2 and process control using redox potential worked well.

Full-scale plant trials at Scottie Gold Mines were carried out with successful results on barren bleed using a stirred tank reactor and Na_2SO_3, the use of which obviated the need for lime.

The new technology is available for licensing through INCO TECH, a business unit of Inco, Ltd.

Gold ore treatment at Emperor Gold Mining Co. Ltd., Vatukoula, Fiji

P. Colbert[1]

INTRODUCTION

Emperor Gold Mining Co. Ltd. operates a 1000 t/day gold ore treatment plant (Fig. 1) at Vatukoula, Fiji. Ore comes from underground and open cut mines (Table 1) and typically averages 5.5 g/t gold. Gold and silver occur mainly as tellurides associated with sulphides, but there is a minor amount of native gold present.

Treatment involves

1. crushing, removal of primary slime, and grinding,
2. flotation of a separate gold-telluride concentrate and a sulphide-gold concentrate from the main ore, and flotation of a concentrate from primary slime,
3. treatment of gold-telluride concentrate for recovery of gold and tellurium as described in Chapter 13, and
4. recovery of gold from sulphide-gold concentrate by roasting and cyanidation.

CRUSHING AND GRINDING

Fig. 2 is a simplified version of the crushing and grinding circuit. Primary crushing is done in a 900 mm by 600 mm Kue Ken crusher. Primary slime is liberated in a 2.1 m by 3.6 m blade mill and removed by screening and rake classification for separate treatment. Plus 35 mm oversize from the Allis Chalmers screen is crushed minus 16 mm by a 1300 mm Symons Short Head cone crusher in closed circuit with a Mogensen sizer. Minus 16 mm screen undersize and rake classifier sand are conveyed to a 2000 t fine ore bin.

TABLE 1

Typical metallurgical figures at Emperor Gold Mining Co. Ltd.

Feed grade*	
Open cut ore	4.1 g/t Au
Underground ore	7.7 g/t Au
Flotation concentrate grade	
Telluride concentrate	2500 g/t Au
Sulphide concentrate	85 g/t Au
Tailing assay	
Final tailing	1.1 g/t Au
Recoveries	
Gold	75%
Silver	20%

* Plant feed comprises 60 per cent open cut ore and 40 per cent underground ore.

[1] Research Metallurgist, Emperor Gold Mining Co. Ltd., Vatukoula, Fiji.

Fig. 1 – General view of treatment plant of Emperor Gold Mining Co. Ltd.

Fig. 3—Telluride, main sulphide, and primary slime flotation circuits of Emperor Gold Mining Co. Ltd.

as shown in Fig. 4. Concentrate is thickened, filtered on a 4-disc Otsuka filter, and then dead roasted in two Edwards 60-rabble roasters. Treatment rate is 26-40 t/day. Roasting is normally autogenous, but oil burners are sometimes needed.

Calcine is given a water wash in a thickener and pumped to a precyanidation agitator where lime is added to give 0.15 per cent CaO in solution; Cyquest is also added. Calcine is then cyanided in three 4.5 m by 3.8 m agitators at 0.05 per cent NaCN.

Cyanided calcine is washed in a thickener and filtered. Thickener overflow and filtrate from the Moore filters is clarified and pumped to a standard Merrill-Crowe circuit for gold recovery. Pregnant solution assay about 1.5 g/t Au and barren solution 0.03 g/t.

Fig. 4—Sulphide concentrate treatment circuit at Emperor Gold Mining Co. Ltd.

Washed calcine is gassed with SO_2 from the roasters to destroy cyanide and to activate unroasted sulphides. The pulp is then aerated and floated as shown in Fig. 4 to recover the sulphides. Flotation is conducted at natural pH (about 6) using copper sulphate, xanthates, and a frother (Table 2). Rougher concentrate joins the main sulphide concentrate and tailing is pumped to the tailing dam.

UNITED STATES PATENT OFFICE

2,240,976

FLOTATION SEPARATION OF MINERALS

Alfred Leslie Bloomfield and Bunting Snowball Crocker, Kirkland Lake, Ontario, Canada, assignors to Lake Shore Mines Limited, Kirkland Lake, Ontario, Canada

Application November 8, 1940, Serial No. 364,789
In Canada November 28, 1938

6 Claims. (Cl. 75—2)

This invention relates to the flotation method for the separation of minerals and is more particularly directed to the conditioning of the mineral pulp to be subjected to flotation in order to overcome the effect of constituents of the pulp which hinder flotation.

Broadly the invention comprises the step of treating the mineral pulp with a roaster gas, preferably formed by the roasting of the concentrates produced by flotation, with a view to overcoming the depressing effect upon flotation of undesirable materials in the pulp.

The invention will be described in relation to the treatment of cyanide tails and with reference to the accompanying drawing which illustrates a flow sheet of a combined flotation and roasting process.

It will be observed that the tailings from the cyanide treatment are conditioned with roaster gases, floated, roasted and returned to be incorporated in the pulp undergoing cyanide treatment for extraction therefrom of gold, or other recoverable values, along with at least a portion of the extraction from the ore itself. A portion of the ore pulp is preferably withdrawn from the cyanide unit and incorporated with the roaster calcines, as indicated, and the mixture is returned to the cyanide unit at a point to allow sufficient cyanide contact to recover the values from the calcines.

In operation the cyanide tailings, as indicated in the flow sheet, or such other ore product as is to be treated, in pulp form is passed through one or more splash or absorption towers 1, preferably in counter-current to the flow of gases from a roaster 2. Various types of splash or absorption towers may be used. In that illustrated the pulp enters at or near the top and is sprayed through a nozzle, or caused to impinge upon a ball or the like located within the tower chamber to disperse the pulp. The pulp spray should contact the walls of the chamber to insure passage of the roaster gases, which are shown as entering adjacent the bottom of the tower, through the pulp and in sufficiently intimate contact therewith to permit the desired pulp conditioning reactions. The pulp preferably flows from the bottom of the tower providing a gas seal as shown.

The pulp may be further conditioned and subjected to agitation, as required, with the addition of desired flotation or frothing agents such as, copper sulphate, xanthates, pine oil or the like, and then passed, by means of a pump or the like, through flotation cells 3 as in usual practice. The flotation tails are discarded as indicated and the concentrates are thickened 5, agitated 6, and passed through a filter 7, preferably equipped with so-called flappers 8 adapted to beat the filter cake to decrease its moisture content. The thus dried concentrate passes to the roaster 2 from which a controlled portion of the roast gases is conveyed through the reaction tower 1, the balance going directly to the stack 9 for discharge to the atmosphere as indicated.

The roasted flotation concentrate is cooled, preferably in the roaster 2, mixed 10 with a portion of the partially treated cyanide pulp and pumped 11 back to the cyanide unit at a point 12, approaching the end of the cyanide treatment, say eight hours before the end of a forty-eight hour treatment. Thus the gold or other value remaining in the calcines is recovered during the final period of the ore treatment.

It will be apparent that cyanide tailings contain lime and cyanide. It is known that these reagents interfere with efficient flotation. The adverse effect of such constituents of the pulp is overcome by the treatment with roaster gas, which changes them to a form which is not deleterious to flotation. The lime is perhaps changed to sulphites or sulphates by the sulphur dioxide in the roaster gas and the cyanide is rendered harmless.

The method is applicable to all cyanide tailings and may be applied to any pulp to be treated by flotation. The cost of treating low grade ores, or the retreatment of tailings and the like, is the determining factor in the commercial possibilities of such mineral products. The present method is particularly economical, effecting a substantial saving in reagent costs and provides an improved more or less cyclical procedure wherein flotation concentrates are used to provide conditioning reagents for the pulp and the roasted concentrates are returned for further cyanide treatment to recover remaining values.

We claim:

1. A method of recovering values from ore products which includes successively cyanide treatment, concentration of the cyanide tailings by flotation, and roasting of the concentrates, characterized in that the pulp formed from the cyanide tailings for flotation is treated with the gases formed by roasting the flotation concentrates.

2. A method as defined in claim 1, wherein the roasted concentrates are returned to the cyanide circuit for retreatment.

3. A method of recovering metals from cyanide

tailings which comprises forming a pulp therefrom, treating the pulp with roaster gases, subjecting the so-treated pulp to flotation and roasting the flotation concentrates to provide the gases for conditioning said pulp.

4. A cyclic method of recovering metals from ore which comprises treating the ore with cyanide, subjecting the cyanide tailings to the action of roaster gases, treating the so-conditioned tailings to concentration by flotation, roasting the flotation concentrates to provide said roaster gases and returning the calcined concentrates to the cyanide circuit.

5. A method as defined in claim 3, wherein the pulp is passed through an absorption tower in counter-current flow to said roaster gases to provide intimate contact between the pulp and the gases.

6. In the cyanide treatment of metal ores, the method which comprises subjecting the cyanide tailings in the form of a pulp to the action of gases formed by roasting at least a portion of the ore to condition the pulp for flotation treatment and thereafter subjecting the so conditioned pulp to froth flotation treatment to recover metal values from said tailings.

Dear Dr. Michaelis:

RE: DESTRUCTION OF CYANIDE IN GOLD MILL EFFLUENTS

Thank you for the information from you report on the Emperor Gold Mine which you sent to me recently.

After reading the description of the gasification process used for the destruction of cyanide, there is no doubt in my mind that cyanide is being destroyed by the well known acidification-volatilization method and not by the newer Inco SO_2-air process. In fact on page 86, your report indicates that SO_2 is used to acidify the pulp and this is confirmed on page 87 where the slurry pH is shown to drop from 9.5 - 2. As you are aware, it is essential in the Inco process to operate at an alkaline pH and maintain that pH by adding lime.

I am making these comments, not with the purpose of protecting Inco's patent claims but rather with the purpose of providing objective comment on how I view the cyanide destruction process being used at the Emperor mine.

.../2

As promised in a recent telephone conversation, I am pleased to send you the summary report of the performance evaluation of the alkaline chlorination process used at three gold mines in British Columbia, carried out by Ker, Priestman and Associates. I am also attaching a paper by J.B. Brodie (Ker, Priestman) and S.A. Zaidi (Environment Canada) based on this study. Should you have any questions regarding this work feel free to contact me again.

Best regards,

NATURAL DEGRADATION AND BACTERIAL PROCESSES FOR CYANIDE REMOVAL

Introduction

Natural degradation of cyanide has been relied upon for years to decompose cyanides and thiocyanate in gold and silver cyanidation effluents. It works well in climates that are warm throughout the year.

SCHMIDT et al. (1981) reviewed these natural degradation processes with particular emphasis on a study conducted on cyanide containing effluent from the DOME Mines at Timmins, Ontario, showing how during summer months cyanide in the barren bleed holding pond at the Dome Mine falls from around 100 mg CN_T/l to less than 0.1 mg CN_T/l due to natural degradation. Several parameters were reported such as temperature in the shallow pond, pH, iron and copper concentrations, etc. This work was continued by SIMOVIC, et al. (1984) who conclude that volatilization of free cyanide and metalls-cyanide decay are the mechanisms that explain cyanide removal during natural degradation. Their paper is inserted below.

EPA Report No. EPA 600/2-78-158 entitled "Investigation of Landfill Leachate Pollution Attenuation by Soils" provides some EPA observations on the attack on cyanide by organic matter which are probably bacterial in nature.

ECHO BAY MINES - LUPIN PROJECT

Several mining companies including several in the far north of Canada rely on natural degradation to destroy cyanide. Echo Bay Mines' Lupen project, for example, employs a huge shallow effluent lagoon for the purpose of impounding effluent during the winter months when little or no degradation is possible and only after degradation of cyanide in summer, releases an effluent. In the northern reaches of Canada with its myriad of lakes and vast open spaces, land is available for such huge impoundments.

The Lupin tailings pond is frozen for much of the year but, in summer, there is a steady wind and 24 hours of sunshine--ideal conditions for natural degradation in a shallow pond. The Lupin tailings decant composition has been the subject of an intense study. Cyanide levels increase noticably from ice break-up until around mid-August when there is a dramatic drop in cyanide levels. North West Territory water effluent limits for cyanide can easily be met and two stages of ponding are likely to be used at the Lupin tailings site. The first pond will allow arsenic removal by $FeSO_4$ addition as well as natural degradation of cyanide. The second will be a polishing pond.

More information can be requested from:

FIGURE 8 – TOTAL CYANIDE IN BARREN BLEED HOLDING POND

ECHO BAY MINES LTD.
10180-101 Street
Edmonton, Alberta T5J 3F4
(403) 429-5885
Hugh Wilson
Manager of Environmental Services

This operation is likely to be the first really well-defined test case of the effectiveness of natural degradation of cyanide in a climate with frozen winters. It looks extremely promising.

However, in some parts of the world there is inadequate land for long term ponding and with the tighter limits that have been imposed on effluents and the given climatic constraints and volumes of water generated from both underground and tailings, there would in numerous cases be no possible way to meet them through natural degradation. One of these is Homestake Mining Company's operation at Lead, South Dakota.

RANDOL CONCEPT FOR ENHANCED NATURAL DEGRADATION OF CYANIDE IN CANADIAN MILL EFFLUENTS

Considering the frequent case where natural degradation is shown to partially remove cyanide from Canadian gold mill effluents in summer. the following concept is proposed as one potential way to ehance the process.

The process may be suitable where:

1) Water is available in abundant supply.

2) Sewage and other nutrients such as phosphates are available at a reasonable cost.

3) Land is available and a natural site is available on which to engineer a bog.

Concept

1) Barren bleed to be stored separately through the winter months in a shallow pond.

2) Tailings pond to be large enough to contain tailings all winter and precipitation without effluent discharge.

3) In Spring raw sewage from a winter accumulation pond, or from local residential area to be pumped into the barren bleed holding pond which should be fitted with an aeration mechanism such as used in municipal water treatment.

4) After aeration of the nutrient enriched barren bleed pond, effluent is pumped to a settling pond where the densest sludges are settled.

5) Solution is next decanted to a large engineered bog of cattails and associated plants with a large surface area designed so that solution passes through a system of trenches in which the plants are grown in a managed fashion.

Aims of Concept

1. To provide a process that will enhance natural degradation of cyanide and metallocyanide complexes.

2. To add a minimum of expensive reagents to the process.

3. To remove total cyanide, metals, and ammonia.

4. To use natural polishing ability of plants if the bog is properly engineered.

ENHANCED NATURAL CYANIDE DETOXIFICATION CONCEPT

Note: The above is a RANDOL INTERNATIONAL LTD. concept that has yet to be tested.

AERATORS

Frings Aeration & Mixing Co., Inc.

2591

OPERATION

The turbine turns inside the stator creating a vacuum at the [illegible] of the turbine. This vacuum is filled with air that enters the [illegible]bine through the standpipe open to the atmosphere. The [illegible]er enters the turbine through openings between the turbine [illegible] the motor. The air and water are mixed in the turbine. The [illegible]ture is discharged into the diffuser channels of the stator. The [illegible]h circumferential speed of the turbine within the stator and [illegible] stator design itself create a fine bubble dispersion of the gas-[illegible]ter mixture with excellent oxygen transfer efficiency and good [illegible]ing. The aerator has two zones of influence:

ZONE A Within this area there is intimate contact of the gas-water mixture with the surrounding waters. This zone would be applicable for sizing air floatation or high BOD loading wastewater treatment processes.

ZONE B There is a complete suspension zone within this area created by the air lift effect of the gas-water mixture. This zone would be applicable for sizing stream oxidation, activated sludge or other normal BOD loading wastewater treatment processes.

Model	DIAMETER IN FEET A Zone Mixing	B Zone Suspension	Aeration Zone
075T	18	30	150
150T	25	40	175
300T	35	65	225
600T	45	75	300
900T	50	90	350
1200T	65	125	375
1800T	70	130	450
2400T	80	140	525

[illegible] influence can be increased by utilization [illegible]ped unit attached to a cable guide. The [illegible] along the cable extending the area [illegible] to a rectangle of approximately 500 feet [illegible] solids and BOD loading [illegible]

TYPICAL SPECIFICATION

Aerator(s) will be submerged, self-aspirating type. The guide blade rim will be of stainless steel construction with a 304 stainless steel turbine.

The motor(s) will have cast iron housing, stainless steel motor shaft, oil filled chamber, double mechanical seal with a seal minder and heat protections. All motors will have 25 feet of electrical cable for hook-up to a 230/460 volt, 3 phase, 60 Hertz electrical system.

The aerator system when put into operation, will provide _____ pounds per hour of oxygen (CWTR) at _____ cfm and _____ foot depth when measured at standard conditions of zero dissolved oxygen, twenty degrees centigrade, and one atmosphere pressure. The design brake horsepower shall not exceed the motor rating horsepower of _____%. The oxygen transfer efficiency at standard conditions at the design depth and air flow will be _____%.

Installation will be made in accordance with manufacturer's specifications. The aeration equipment manufacturer will provide start-up services of a qualified technician or engineer.

The manufacturer guarantees that the aeration equipment will operate as specified above. The manufacturer will be responsible for equipment design, material and workmanship for a period of one year from date of start-up, not to exceed 18 months from date of shipment. The manufacturer will not be liable for contingent damages caused by malfunction of the equipment.

ACCESSORIES

SERVICE FLOAT

The float consists of 17 or 26 inch gull wing floats filled with a closed cell polyurethane. The urethane filler makes this rugged assembly virtually unsinkable. The service float has non-skid grating and a hand winch for lift.

MOTOR CONTROLS

Control centers are engineered specifically for use with Framco aerators. Each control center contains visual or audible indicators for the safety devices. Every control center is designed to meet the requirements of the specifying engineer or controlling agencies. All control centers are available with standard outdoor enclosures.

AIR INLET PIPE

Carbon steel or PVC pipe is available with or without an air throttling valve. A hooded wire mesh screen or air filter, can also be provided.

SUPPORT LEGS

Three or four legs, depending on the model, can be provided, to clear bottom objects. The legs are steel pipe with stainless steel hardware.

ADDITIONAL ACCESSORIES

Suction Strainer — Semi-Bridge
Suction Silencer — Lifting Device Including Hoist
Guide Brackets — Steel Lifting Lugs Including Clamp and Bolts

DEVELOPMENT OF A MODEL TO DESCRIBE THE NATURAL DEGRADATION OF CYANIDE IN GOLD MILL EFFLUENTS

By L. Simovic*, W.J. Snodgrass**, K.L. Murphy***
and J.W. Schmidt*

ABSTRACT

Natural degradation is the oldest treatment method used by Canadian gold mines to remove cyanide from their effluents. This paper presents the results of a study carried out to determine the main mechanisms which control the natural degradation of cyanide, and to develop a mathematical model for predicting cyanide degradation in gold mill effluents.

The most important mechanism in the natural degradation of cyanide was recognized as being volatilization. Among the variables affecting the degradation process, the three identified as most important were selected for study, namely: temperature, UV light and aeration. Temperature had the largest effect upon reaction kinetics and ultraviolet irradiation had a significant effect upon the decay rate of the iron cyanide complex.

Synthetic solutions of simple cyanide (NaCN) and metallo-cyanide complexes of Cu, Zn, Ni and Fe were used in bench-scale tests to generate the data for estimating kinetic parameters for the model. In addition, tests were carried out on synthetic solutions and actual gold mill effluents, to calibrate the model and evaluate its effectiveness in predicting cyanide degradation in a variety of aqueous solutions.

The mathematical model, developed during this study, fitted the experimental data at the 95% confidence level for five of the eight tests on synthetic wastewaters. Using coefficients derived from the synthetic solutions, the model was applied to actual gold mill effluents. It predicted the degradation of cyanide from tailings pond water very closely, but for the barren solutions it required further recalibration. The use of the model as a design tool is illustrated.

BACKGROUND

In most Canadian gold mills, gold is extracted from the ore by the process of cyanidation. The waste streams from the process contain, among other impurities, a high concentration of cyanide and heavy metals making treatment essential prior to discharge to the environment.

---

* Environment Canada, Environmental Protection Service, Wastewater Technology Centre, Burlington, Ontario
** McMaster University, Hamilton, Ontario
*** IEC Beak Consultants Ltd., Toronto, Ontario

The oldest treatment practised by Canadian gold mines for destruction of cyanide is natural degradation. In this method, cyanide-bearing waste streams are impounded, usually in a tailings pond, for a period of a few days to several months, while the process of natural degradation of cyanide occurs (Scott and Ingles, 1981). Although natural degradation has been practiced for many years, the process chemistry has not been well documented. In 1979, Environment Canada's Wastewater Technology Centre in Burlington, Ontario, carried out an extensive sampling program at one Canadian gold mine (Schmidt et al, 1981). The results of this study indicated that the main mechanisms of cyanide removal were volatilization of free cyanide (90%) and chemical oxidation (10%). To better delineate the main factors and mechanisms affecting the process for design purposes, a bench scale study was recommended.

In this study, the removal of total cyanide from synthetic metallo-cyanide complex solutions was evaluated experimentally at the Wastewater Technology Centre in Burlington. This evaluation utilized (i) an experimental design to determine the main factors controlling cyanide removal; (ii) the development of a mathematical model to describe cyanide removal and (iii) the application of this model to synthetic solutions containing a mixture of metallo-cyanide complexes. Finally, this model was applied to actual gold mill wastewaters, barren solution and tailings pond water. For illustrative purposes, the model was used in a hypothetical design.

EXPERIMENTAL DESIGN

The literature generally indicates that the mechanisms of volatilization, hydrolysis, dissociation, photodegradation, chemical and bacteriological oxidation and precipitation-dissolution may have important influences on the process of natural degradation of cyanide in ponds depending on the cyanide species present and physicochemical conditions (Leduc et al, 1982).

Palaty and Horokova-Jakubu (1959) examined several factors that affect HCN removal from unbuffered, synthetic simple cyanide solutions(KCN) at relatively low concentrations (10-50 mg CN^-/L) over a period of 11 days. They were pH, temperature, solution depth, presence or absence of aeration and the rate of aeration. Their general conclusions were: the HCN removal rate increases with decreasing pH down to 5; an order of magnitude difference in the rates of HCN removal exists between aerated and nonaerated solutions; the HCN removal rate is indirectly proportional to the solution depth and almost directly proportional to the rate of aeration; a temperature increase of 10°C (from 0.8 to 11°C) causes the HCN removal rate to increase by >40% (from 0.112 to 0.216 h^{-1}).

Based on a review of the literature and a set of screening experiments, the three most important variables influencing cyanide removal were incorporated into a factorial experimental design; temperature, UV light and aeration. The high and low levels were chosen as reasonable approximations of what might be expected under actual conditions.

A full 2^3 factorial design (Box et al, 1978) was used (Table 1) to determine which variable had the greatest effect on the rate of cyanide degradation. In total, 56 runs were made for up to 13 days in duration.

METHODS AND MATERIALS

Seven synthetic cyanide solutions were used in one set of laboratory tests. These consisted of a simple cyanide solution (NaCN), four solutions containing a single metallo-cyanide complex (Cu, Zn, Ni and Fe) and two mixtures. The "low mix" contained a low concentration of metals relative to the concentration of total cyanide, i.e. a metal cyanide (MCN) to total cyanide (TCN) weight ratio of 0.17, while the "high mix" was saturated with metals (MCN/TCN = 1.17). The initial total cyanide concentration in all the solutions was about 200 mg/L. The experiments were carried out in 2000 mL graduated cylinders at two different temperatures (4°C and 20°C). The experimental pH chosen was 7.0; a phosphate buffer was used to maintain a constant pH.

Barren solution was also tested in the laboratory with a similar experimental setup (20°C, AIR, UV). For the tailings pond water, a field experiment was conducted using a large tank located outdoors.

Total cyanide was analyzed by the methods described by Conn (1981). Heavy metals were analyzed by atomic absorption spectroscopy (AAS).

RESULTS AND DISCUSSION OF EXPERIMENTS ON SYNTHETIC CYANIDE SOLUTIONS

Upon completion of the experiments, plots of temporal changes in total cyanide concentrations in the single metallo-cyanide solutions were prepared and examined visually. Specific examples of these plots with the general trends are given in Figure 1. In several tests the residual total cyanide concentration attained was <1 mg/L (see the NaCN and Cu-CN examples); in most tests it was <10 mg/L (see the Fe-CN example) but in some cases the concentration seemed to plateau between 30 to 40 mg/L; (see the Ni-CN example).

The initial rapid decrease in cyanide concentration (first part of the curve), was observed to be complete after 48 to 72 hours under all experimental conditions. This was assumed to be controlled by the volatilization of free cyanide from the solutions.

The slope of the second part of the curves varied among the different metals and experimental conditions. This was assumed to result from the different rates of dissociation or decay of these metallo-cyanide complexes. Thus, the graphs suggest that volatilization controls the cyanide removal rate during the first part of the curve but metallo-cyanide dissociation controls the removal rate during the latter part of the curve.

To interpret the data, first-order reaction kinetics were applied to each of the two parts of the curve. By using linear regression, the volatilization mass transfer coefficient, k_v, was determined for the first part of the curve and the metallo-cyanide decay coefficient, k_1, for the second part of the curve. These coefficients were used as the response variables in the factorial design. The main effects and the two and three factor interactions were determined. Since no replicate runs were conducted, the three factor interaction was used as the estimate of error variance. Temperature was found to have a significant effect (5% level of significance) on the rate of volatilization of free cyanide from all metallo-cyanide solutions and together with aeration a high effect on volatilization of free cyanide from NaCN solution. In addition, temperature had a significant effect on the metallo-cyanide decay process in all metallo-cyanide solutions except iron cyanide and the "low mix", where UV light had the largest main effect (Simovic, 1984).

MODEL DEVELOPMENT

The second objective of the study was to develop a mathematical model with predictive capabilities. Because the measurements of cyanate made during the experimental runs showed that there was no CNO^- present, it was decided that chemical oxidation of cyanide to cyanate was not an important mechanism.

The concentration of total cyanide in the aqueous solution was the only parameter that was measured in the experiments. Total cyanide is the summation of all the different cyanides (metal and free) that exist in solution (TCN = MCN + FCN).

FIGURE 1. TYPICAL RESULTS OF TOTAL CYANIDE DEGRADATION IN Fe, Cu, Na AND Ni CYANIDE SOLUTIONS

The initial study results coupled with the available literature suggested that a mathematical model should be based upon the following:

1 - Metal cyanide complexes dissociate into metallic and cyanide ions ($MCN \rightarrow M^+ + CN^-$).
2 - Cyanide ions, in a reaction with hydrogen from water, produce HCN. The equilibrium developed between CN^- and HCN is pH dependent ($CN^- + H^+ \rightleftharpoons HCN$).
3 - The dominant form of free cyanide at pH 7.0 is molecular HCN. Molecular HCN is the species that volatilizes.
4 - Temperature influences the rate of decay of most metallo-cyanides. UV light affects the dissociation of iron-cyanide complexes.

To develop a model for a single metallo-cyanide complex solution, each chemical species containing cyanide was considered to be a separate component. A schematic of the various forms of cyanide that are included in the total cyanide (TCN) measurement and the proposed transformations is given in Figure 2.

FIGURE 2. CYANIDE DEGRADATION MODEL

The first component in Figure 2 is the metallo-cyanide complex (MCN), the second is the cyanide ion (CN^-) and the third is molecular hydrocyanic acid (HCN). If the second and third are taken together they represent free cyanide (FCN). Each arrow between the components represents a transformation of mass. It has been assumed that one metallo-cyanide complex (rather than two or more complexes) and free cyanide can explain the observed characteristics of cyanide loss from solution in the single metallo-cyanide solutions. The coefficients k_1, k_2, k_3 are the rate constants (h^{-1}) of transformation between the

different forms; k_v is the volatilization mass transfer coefficient (cm/h), while k_{uv} represents the additional effect upon k_1 due to ultraviolet irradiation (h^{-1}).

Evaluation of the model schematic (Figure 2) shows that there are three potential steps (i.e. parameters) which can control the rate of removal of cyanide from solution. They are the rate of dissociation of MCN, the rate of formation of free cyanide (HCN and CN^-) and the rate of volatilization of HCN. Since the kinetics of HCN formation from CN^- and its dissociation to CN^- are extremely rapid (Caruso, 1975):

$$[HCN] \rightleftarrows [H^+] + [CN^-] \quad K_a = 4.36 \times 10^{-10} \text{ (at 20°C)}$$

the formation of HCN is not rate limiting. This allows one to treat HCN and CN^- as being constantly in equilibrium relative to other processes. Hence, there are two potential rate controlling steps, and the model to be derived can be represented by a two compartment reaction-in-series model.

For a batch reactor, the mass balance equations are:

- for metal cyanide

$$\frac{d[MCN]}{dt} = -k_1 [MCN] - k_{uv} [MCN] \qquad (1)$$

- for free cyanide (sum of CN^- and HCN)

$$\frac{d[FCN]}{dt} = k_1 [MCN] + k_{uv} [MCN] - \frac{k_v}{Z_h} [HCN] \qquad (2)$$

where $Z_h = V/A_s$. Here A_s (cm^2) is the area of the air-water interface across which volatilization occurs, and V is the reactor volume (cm^3). If the UV light effect is insignificant, k_{uv} becomes zero.

Summing these two equations produces one for total cyanide:

$$\frac{d[TCN]}{dt} = -\frac{k_v}{Z_h} [HCN] \qquad (3)$$

These three equations represent the derived model.

PARAMETER ESTIMATION

To solve the differential equations (1 to 3) a numerical integration routine was applied using the Runge-Kutta-Verner fifth and sixth order method (DVERK) available from the International Mathematical and Statistical Libraries Inc. for CYBER systems. This method requires that the initial conditions be known, then calculates simultaneously the change of concentration over time for total, metallo- and free cyanides using in this case, ten-hour time increments.

The initial value for TCN was set equal to the measured TCN concentration. Three parameters were estimated: initial metal cyanide concentration $[MCN]_o$, metallo-cyanide decay coefficient (k_1), and the volatilization coefficient (k_v). In order to determine the initial value for the volatilization rate, linear regression analysis was applied on the first part of the degradation curve and the 95% confidence interval (C.I.) was then calculated. The rate of volatilization of HCN from single metallo-cyanide solutions was found to be within the 95% C.I. of the volatilization rate of HCN from NaCN solution. Therefore, the value calculated as the volatilization rate of free cyanide from NaCN solution was used in parameter estimation and modelling work. The metallo-cyanide decay coefficient, k_1, previously determined, was used as an initial value.

To obtain the best estimates of the parameters for the model, an iterative, nonlinear least squares parameter estimation subroutine was used (GAUSHAUS*).[2] It is based on Marquardt's method which combines the Gauss method (Taylor series) and the method of steepest descent (Meeter and Wolfe, 1965).

From the estimated parameters the ratios of initial concentration of metal cyanide (MCN_o) to the initial total cyanide concentration (TCN_o) were calculated under all experimental conditions and compared to the theoretical value of MCN/TCN = 0.17. The results are presented in Table 2. Despite the range of MCN_o/TCN_o values from

TABLE 2. THREE PARAMETER ESTIMATION MODEL (MCN_o, k_1, k_v)

Cu - CN	$\frac{MCN_o}{TCN_o}$ = 0.07 to 0.69 R^2 (%) = 97 to 99
Zn - CN	$\frac{MCN_o}{TCN_o}$ = 0.12 to 0.74 R^2 (%) = 98 to 99
Ni - CN	$\frac{MCN_o}{TCN_o}$ = 0.11 to 0.53 R^2 (%) = 96 to 99
Fe - CN	$\frac{MCN_o}{TCN_o}$ = 0.12 to 0.41 R^2 (%) = 98 to 99

* GAUSHAUS now called UWHAUS

0.07 to 0.74, the calculated multiple correlation coefficient, R^2, indicated that 96 to 99% of the total variability in the data was explained by the model.

To determine whether these estimated values were statistically different from the theoretical ratio for MCN/TCN of 0.17, the model was fitted using different MCN/TCN ratios (0.0425, 0.085, 0.17, 0.34, and 0.68). The initial metallo-cyanide concentration, $[MCN]_o$, k_v, and k_1 were estimated for each ratio for all experimental conditions. Analysis of the residual sum of squares (RSS plotted versus ratio) using an F test, showed that the model fit obtained in 27 out of 32 conditions (4 metals and 8 conditions) in the first analyses was not significantly different (5% level of significance) from the fit obtained for the stipulated ratio MCN/TCN of 0.17. It was concluded that the theoretical MCN/TCN weight ratio of 0.17 could be used for the initial ratio in the laboratory solutions of single metallo-cyanides.

The estimated metallo-cyanide decay coefficients were averaged for experiments at 4°C and 20°C (Table 3). This was justified because the temperature had a significant effect on metallo-cyanide decay rates, aeration had no effect, and ultraviolet light had a significant effect only on the Fe-CN and "low mix" solutions.

TABLE 3. AVERAGE METALLO-CYANIDE DECAY COEFFICIENTS (h^{-1})

	$k_1 \times 10^2$ (4°C)	$k_1 \times 10^2$ (20°C)
Zn-CN	1.78	4.49
Cu-CN	0.29	0.75
Fe-CN	0.14	0.47
Ni-CN	0.04	0.09

The Zn-CN decay rate was the fastest (an order of magnitude more rapid than Cu-CN); decay of Cu-CN was double that of Fe-CN, while Ni-CN was an order of magnitude slower than Cu-CN and Fe-CN.

VERIFICATION STUDY - LOW MIX

The averaged metallo-cyanide decay coefficients (Table 3) were used in the simulations for the "low mix" solutions. The "low mix" solutions should theoretically contain 17% of the total cyanide complexed with the four metals present.

A typical comparison of model predictions and observations is presented in Figure 3. There was good agreement between the model and observations during the volatilization of free cyanide (first 70 h of the curve) and during the degradation of metallo-cyanides in the latter part of the curve. Overall, the model predictions agreed with the observations at the 5% level of significance for five out of the eight sets of experiments performed on the "low mix", however, for the other three, agreement was not as good.

FIGURE 3. LOW MIX SIMULATION - 20°C, NO AIR, UV

EVALUATION OF THE MODEL WITH GOLD MILL EFFLUENTS

The model derived from synthetic solutions was tested on data on effluents from two Canadian gold mines (batch systems). One effluent was a barren solution (bench scale experiment), and the second was tailings pond water (field experiment). Data describing the characteristics of these solutions at the beginning and at the end of the experimental period are given in Table 4.

TABLE 4. CHARACTERISTICS OF GOLD MILL EFFLUENTS (BEFORE AND AFTER TREATMENT)

Gold Mill Effluent Type	TCN (mg/L)		pH		Cu_T (mg/L)		Zn_T (mg/L)		Ni_T (mg/L)		Fe_T (mg/L)		RT (d)
	I	F	I	F	I	F	I	F	I	F	I	F	
Barren Sol'n.	145	2.3	11.5	8.2	7.1	7.1	31	21	1.5	1.3	0.1	<0.1	55
Tailings Pond Water	4.3	0.2	8.2	8.1	0.7	0.3	0.1	<0.1	0.2	<0.1	1.0	0.6	65

RT - Retention time; I - Initial value; F - Final value

The apparatus used for the barren solution was the same as the one used for the synthetic solutions (2000 mL graduated cylinder). The experiment was conducted in the laboratory under the best conditionsfor the natural degradation of cyanide, i.e. 20°C, AIR and UV. During the retention time of 55 d, the concentration of total cyanide in this solution decreased 98%, from 145 to 2.3 mg/L (Table 4). The pH changed from 11.5 to 8.2 during the same time period.

The apparatus used for the tailings pond water was an open circular tank with a diameter of 7.3 m and a depth of 1.6 m. It was exposed to natural environmental conditions from July to October of 1983. The effluent was aerated with compressed air, at an air flow rate of 0.3 m^3/min. The initial concentration of total cyanide in this effluent was significantly lower than in the barren solution. During 65 d, the total cyanide decreased 95% from 4.3 to 0.2 mg/L (Table 4).

The only differences that existed between these gold mill effluents and synthetic solutions were the initial cyanide and metal concentrations, the pH of the solutions, and the depth of the experimental vessel used for the tailings pond water. To model these effluents it was assumed that the actual gold mill effluents contained the same metallo-cyanide complexes as the synthetic solutions (i.e., $Cu(CN)_3^{2-}$ $Zn(CN)_4^{2-}$ $Ni(CN)_4^{2-}$ $Fe(CN)_6^{3-}$). An adjustment to the model was required because of the difference in pH values. Since the model equations were derived for synthetic solutions at pH 7.0, corrections for volatilization rate were required to account for the pH dependent speciation of HCN (i.e. $HCN \rightleftharpoons H^+ + CN^-$). A second adjustment involved the effect of solution depth on the volatilization coefficient in equation (2).

The results of the model simulation on cyanide degradation in barren solution are presented in Figure 4a. Considering the initial cyanide value (145 mg/L), the model predictions fitted the data well particularly during the volatilization process (first part of the curve). However, as inspection of the latter part of the curve shows, the model predicted a more rapid decay of the metallo-cyanides than actually occurred. There are three possible reasons for this discrepancy. Firstly, it was originally assumed that the effect of pH on the metallo-cyanide decay rate was insignificant and that the main effect of pH was upon HCN and CN^- speciation. In fact, the pH may affect the decay rate. Secondly, the barren solution may contain different metallo-cyanide complexes than the ones assumed. Thirdly, at the high pH values (i.e. 11.5 and 8.2), the cyanide ion released upon metallo-cyanide dissociation could not form HCN, therefore, it could complex with another metal or even form thiocyanate and precipitate. The metal would be more successful in competing for CN^- at high pH than the H^+ form. The model would not account for these conditions.

The final value calculated by the model for TCN was compared to the experimental value observed for TCN in Table 5. The predicted TCN

FIGURE 4. SIMULATIONS ON BARREN SOLUTION -
a) ORIGINAL b) RECALIBRATED k_{Zn} AND k_{Ni}

for the barren solution was lower than the value obtained in the experiment. Similarly, the predicted break-point between volatilization and metallo-cyanide decay occurred earlier than observed from the barren solution experiment (see Figure 4a: deviation from curve at about 225 h).

TABLE 5. RESULTS OF THE SIMULATIONS ON ACTUAL GOLD MILL EFFLUENTS

Gold Mill Effluent Type	Time (h)	TCN (mg/L)	
		Expt.	Predicted
Barren Solution	1320	2.3	0.75
Tailings Pond Water	1560	0.1	0.05

In the experiments on single metallo-cyanide solutions there was variability in the volatilization rates, and in the metallo-cyanide decay rates for the same experimental conditions. A similar degree of variability can be expected in model predictions involving actual effluent data. Hence, to obtain a better fit for the barren solution data, some model recalibration from the mean parameter values of the single metallo-cyanide solutions can be expected to be required.

Inspection of the characteristics of these two effluents (Table 4) showed that the barren solution contains a higher concentration of nickel. Nickel was found to be the slowest degrading metallo-cyanide complex (Table 3). When the reaction rate constant for Ni was recalibrated (from 0.00095 to 0.00024 h^{-1}, obtained from an examination of the curve) the predicted metallo-cyanide decay part of the curve improved considerably (predicted TCN = 1.9 mg/L). However, there was no significant change in the location of the volatilization-metallo-cyanide decay break-point on the curve.

It was also noted (Table 4) that for the barren solution, the concentration of Zn was the highest of all the metals. It also has the fastest degradation rate (Table 3). Accordingly, it was hypothesized that the Zn-CN in the barren solution controls the location of the break-point. When the reaction rate constant for Zn was recalibrated (from 0.045 to 0.009 h^{-1}, obtained from an examination of the curve) the agreement of the model predictions with the data improved considerably (Figure 4b: better fit at about 225 h).

The model prediction for the tailings pond water (Figure 5) was considerably better than for the barren solution. Because the total cyanide concentration was very close to the calculated metallo-cyanide concentration, cyanide degradation was controlled by the metallo-cyanide decay stage. Therefore, model calculations for volatilization had little effect upon the shape of the curve.

FIGURE 5. SIMULATIONS ON TAILINGS POND WATER

The results obtained from modelling actual gold mill effluents validate the original idea, that the rate of volatilization and the rate of metal decay, control the process of degradation. Recalibration of the reaction rate constants, for particular barren solutions, appears to be necessary to achieve good agreement with observations, owing to the complexity and variability of different natural solutions. An assessment of the frequency and degree of recalibration to be expected must await further model testing.

MODEL APPLICATION

The purpose in producing the model was to develop a design tool for natural degradation systems. To illustrate its use, it was assumed that two systems could exist: (i) a batch system, representative of a holding pond filled with barren solution and allowed to sit over summer to degrade naturally; and (ii) a continuous stirred tank reactor (CSTR) system, representative of a tailings pond, having a continuous inflow and discharge with a retention time (RT) of 3 days. The total cyanide concentration in the influent to the tailings pond is low in the winter time, because the barren solution is stored in a separate pond. However, in the summer time the influent cyanide concentration is higher because the barren solution is also fed into the tailings pond.

For the batch system, an effluent objective of 0.05 mg/L total cyanide was required. From the estimated rate constants of the metallo-cyanides (Table 3), nickel-cyanide is the complex that degrades the slowest. Therefore, the required retention time was calculated, applying the derived model equations to a batch reactor, for the worst conditions, i.e. decay of nickel-cyanide complex. The retention time necessary to achieve this effluent objective was calculated to be 5.8 months in the summer (20°C). This value agrees well with the actual results attained at a Canadian gold mine (barren solution holding pond volume V = 6000 m^3) where a concentration of 0.05 mg/L was reached after 5.5 months (Schmidt et al, 1981).

For winter conditions (at 4°C) and the same effluent objective, the retention time calculated was 12.5 months. The approximate CN degradation during this time would be 97% of Ni-CN, and 100% of the other three metallo-cyanide complexes (Cu, Zn and Fe), and the free cyanide. This result cannot be compared to any existing system in Canada, because no pond in Canada would remain at 4°C for one year. Further, most ponds are either filled during the winter, thus preventing them from being considered as a spiked, batch system, or are frozen solid during winter months and thus no data on TCN is available.

For the tailings pond (CSTR), two time periods were examined, summer and winter. The initial TCN concentrations, presented in Table 6, were the real mean values from a similar system at a Canadian gold mine (MCN/TCN = 0.6).

Assuming steady state conditions and using the previously derived model based on first order kinetics, the concentration of TCN was calculated for four different retention times (Table 6), and plotted in Figure 6. The predicted TCN concentration after three days during winter would be 32.8%, and for summer 43%. In the actual system, the corresponding values were 43.6% and 73.1% respectively. The difference between the predicted and observed values may be explained by the following: the actual system is probably not under steady state conditions, it is not represented by a true CSTR, and solid particles are present.

TABLE 6. CALCULATED TCN FOR THE TAILINGS POND

Retention Time (d)		0	1	3	7	30
Winter	Average input TCN_o = 14 mg/L	Calculated TCN_F concentration (mg/L)	11.7	9.4	7.4	3.9
	% removal		16.4	32.8	47.1	72.1
Summer	Average input TCN_o = 22.3 mg/L	Calculated TCN_F concentration (mg/L)	17.2	12.7	8.9	3.9
	% removal		22.9	43.0	60.1	82.5

F - Final concentration

FIGURE 6. CYANIDE DEGRADATION - DESIGN CALCULATION

CONCLUSIONS

The conclusions from this study are:

1) Volatilization of free cyanide and metallo-cyanide decay are the mechanisms used to explain cyanide removal from solution during natural degradation. Volatilization is a rapid process, thus metallo-cyanide decay will be the rate limiting mechanism for many conditions.

2) Analysis of the experimental results conducted on laboratory solutions show that temperature appears to have had the greatest effect on the volatilization rate of both NaCN and metallo-cyanide solutions. Aeration had a lesser effect than temperature on the volatilization of free cyanide from NaCN solutions. Volatilization was essentially complete within the first 48 to 72 hours of the removal process.

3) Temperature had a large effect upon the metallo-cyanide decay rate in most of the solutions. UV light had a large effect only on the Fe-CN and "low mix" solutions containing low quantities of iron. It had no significant effect upon a "high mix" solution containing a high concentration of iron.

4) A mathematical model, developed for the degradation of a single metallo-cyanide complex solution in a batch reactor, supported the assumptions that the volatilization of free cyanide and metallo-cyanide complex decay controlled the cyanide degradation process, and that a chemical equilibrium existed between HCN and cyanide ion.

5) By using the best estimates of the reaction rate coefficients determined for the single metallo-cyanide solutions to simulate the experimental data of the mixed synthetic metallo-cyanide complex solution, it was found that the model predictions fitted the data at the 95% confidence level in five of the eight test conditions, however, for the other three, it did not fit as well.

6) The model derived from the synthetic solutions was applied to two gold mill effluents. In the case of modelling tailings pond water containing a very low level of total cyanide, the results showed that the model can be used successfully to estimate the cyanide degradation rate. For barren solution, although the model predictions generally fitted the data well, recalibration of the rate constants was considered necessary.

7) The model derived for batch reactors, can be used at this stage of its development, for design purposes.

Re: Your letter 3 October, 1984 - Natural Degradation of Cyanide

In response to your question concerning the location of the "final effluent" sampling point (3A), I would advise that it was located near the toe of the tailings dam. There was no dilution of the effluent at this location and the residence time in the decant structure was perhaps of the order of a few seconds. As tailings ponds III and IV were not used simultaneously the same comment applies to sampling location 3B.

I cannot give you a definitive answer to the first sentence in your fourth paragraph. The reason for this is that two gold mills located in the Northwest Territories (N of 60° latitude) have, in fact, proposed to use this method as the "sole means" of treatment. Both mines have been operating for a period of about two years and their tailings ponds are of such a size that they will not have to decant any water for a period of several years. We are collaborating with both mines on "natural degradation" studies and they are also undertaking on-site test work to determine whether or not "natural degradation" will be an adequate "sole treatment" process. Because both these mines are very isolated the cost of any chemical treatment would be quite substantial. We are also aware that other operators are or intend to use "natural degradation" as an element of their treatment systems.

Since presentation of our paper on natural degradation, we have carried out additional laboratory and field studies with a view to developing a model for design purposes. I regret, however, that this information is not yet readily available but will be published in several different reports and papers in the next few months and we will be pleased to forward this information to you when it becomes available. A major paper summarizing most of the work will be presented at the "Cyanide and the Environment" Conference being held in Tucson

In order to conserve energy and resources, this paper contains post-consumer fibre.

A des fins de conservation de l'énergie et des ressources, ce papier contient des fibres recyclées.

Mr. H. Von Michaelis October 22, 1984

in December, by Mrs. L. Simovic, the project leader for our natural degradation studies. Much of the information to be presented will be from her M.Eng. thesis (a 350 page document) which she recently completed.

The document which you are compiling looks as though it would be of interest to us and we would appreciate being advised when it is completed. } Sadly Not possible *

We thank you for your interest in our program and if we can be of additional assistance (with respect to this topic or minewater treatment generally, please do not hesitate to contact us.

Yours very truly,

HEAP LEACHING

Most heap leaching operations to date have been located in parts of the country with net evaporation, and it is reasonable to expect that cyanide will be destroyed by natural degradation in these heaps on abandonment. The question has been raised that if a heap is drained, there will still be cyanide left in the pores of rock particles and the residual moisture content of the material. As this dries out and water evaporates, cyanide will be left as soluble salts. If dry, it will remain forever, and the question is asked as to its fate if some years later there is a torrential downpour. This aspect is under investigation. To date, Dave Milligan is the only person known to have actually sampled material from the inside of abandoned heaps to measure its cyanide content on one dump.

It is reasonable to speculate that the fate of cyanide in abandoned heaps will be one of three:

1) Natural degradation will cause cyanide to be lost as the heap dries out. There will always be some residual moisture left, and atmospheric CO_2 will reduce the pH low enough to volatize cyanide.

   Also, bacterial action in the heap with its large surface area will consume cyanide as an energy source in some cases.

2) Where small amounts of sulfides are present in the tailing material, oxidation thereof in the dam material exposed to the air will cause a pH drop in the residual interstitial moisture which will slowly volatilize residual cyanides which will be lost.

3) If the pH stays high at around pH 10 or so, there is a possibility that some residual cyanide values could reside in the heap for some time until precipitation flushes it out. This has not been studied or confirmed, however.

With the third possibility in mind and for heap leaching operations in parts of the world with net precipitation, there are two possible approaches:

1) Rinse the heap with alkaline hypochlorite solution before abandonment as at Superior Mining, Idaho--see Appendix I.

2) Use the heap material as a giant trickle filter.

By irrigating solutions onto the heap that are innoculated by appropriate bacteria and nutrients, the biological oxidation of residual cyanide can likely be enhanced.

This concept emerged at the RANDOL Water Workshop, Beaver Creek, in October, 1984. It is now being tested at a New Mexico heap leaching operation by:

HOMESTAKE MINING COMPANY, LEAD, SOUTH DAKOTA

Following the imposition of relatively strict effluent limits by the state of South Dakota in 1976 a major effort has been underway to meet the regulatory demands. The various processes tested have been described by HALBE et. al. (1979); TRAUTMAN & OMMEN (197?); MUDDER & WHITLOCK (1984) and WHITLOCK & MUDDER (1984). The historical battles between the company and the regulatory authorities in trying to gain relief from limits that appear almost impossible to meet by any known technical process that could be afforded were described by EDELMAN & WALLINE (1981)

Parameter	BPT Limit (40 CFR 440.22)* mg/l	WQS Limit mg/l	Permit
Total Suspended Solids	30	10	10
Arsenic	N/A	0.38	0.38
Cadmium	0.1	0.00025	0.00025
Chromium	N/A	0.85	0.85
Copper	0.1	0.009	0.009
Lead	0.4	0.28	0.28
Mercury	0.002	0.001	0.001
Nickel	N/A	1.25	1.25
Silver	N/A	0.001	0.001
Zinc	1.0	0.020	0.020
Cyanide	0.02	**	0.02
pH	6 to 9	N/A	6 to 9

* 40 Fed. Reg. 61722 (Nov. 6, 1975).

** "Quality Criteria for Water," United States Environmental Protection Agency (July 1976), indicated that an instream value of 0.005 mg/l total cyanide would be necessary to protect fresh water aquatic life. With the available dilution ratio, this would require and effluent limitation of approximately 0.017 mg/l.

Source: EDELMAN & WALLINE

Since 1981 or 1982 Homestake Mining Company redirected its cyanide removal development and search towards biological processes. The laboratory and pilot scale test program has culminated in a commercial scale plant to treat a maximum of 21,000 m^3d (3800 USgpm) of mine and tailings decant water by biological processes employing 48 rotating biological contactors in a plant rumored to cost somewhere between $5.5 million and $10.0 million depending on the source.

MUDDER & WHITLOCK (1984) and WHITLOCK & MUDDER (1984) have provided a glimpse at the broad principles of the process and have also discussed some of the shortcomings of other processes that have been tested or evaluated. Their papers describe the basic process details but since the plant has been operating less than one month at the time of writing it is too soon to determine what performance can be achieved. Bacterial colonies take several months to stabilize.

FEED SOLUTION AT LEAD, SOUTH DAKOTA

Wastewater Characteristics

PARAMETER	MINEWATER[1]	TAILINGS IMPOUNDMENT WATER[1]
Thiocyanide	1.0 - 16.0	110.0 - 240.0
Total Cyanide	.10 - .50	7.00 - 30.00
Method-C Cyanide	.02 - .10	4.00 - 20.00
Iron	.10 - 10.00	1.50 - 6.00
Copper	.07 - 1.60	1.40 - 6.00
Nickel	.01 - .04	.20 - .40
Zinc	.01 - .10	.01 - 1.50

POTENTIAL SUITABILITY

Suitability of Bacteria for Removal of

Total Cyanide CN_T	Thiocyanate CNS^-	Method-C Cyanide	Ammonia	Metals
Yes	Yes	Yes	Yes	Yes

MUDDER & WHITLOCK (1984) showed that acclimatized strain of bacteria could remove all the items of major concern in the Homestake effluent. Ammonia in the minewater and ammonia generated in the biodegradation of cyanide could be removed in a second stage biodegradation step to yield NO_3^-.

WASTE WATER TREATMENT USING ACCLIMATIZED PSEUDOMONAS PAUCIMOBILIS

84-06156 M1

Biological degradation of free or complex cyanide and thiocyanate - waste-water treatment using acclimatized Pseudomonas paucimobilis (En)

/Homestake-Mining/ US 4440-844: 20.04.83-US-486610 (03.04.84) 20.04.83 as 486610. *84-100770/16*

The strain Pseudomonas pausimobilis (Mudlock) ATCC 39204 is used in the degradation of cyanides, thiocyanates and metal cyanide complexes in aqueous waste. The aqueous waste is contacted with this flora to cause conversion of harmful cyanides etc. to environmentally safe products. Preferably contact is in a rotating biological contactor where the flora is attached to a rotating disk so that part of the disk is in the waste and part in the air. Alternatively, an activated sludge method is used where the flora and waste are alternately agitated and settled with continuous aeration. The wild type strain is preferably acclimatized in a medium containing 5-15 mg/l total cyanide and 30-70 mg/l thiocyanate. The process is used for treating mining and electroplating waste-water. The pollutants (including stable Fe complexes) are oxidized to bicarbonates, sulfates and nitrates without generating ammonia. (6pp)

MICROBIOLOGICAL PROCESS

MUDDER & WHITLOCK isolated a specific strain of bacteria indigenous to process waters at the Homestake Mine. These were acclimated to increased concentrations of cyanide and thiocyanate to develop a mutant strain with increased capacity to degrade cyanides.

The bacteria species developed are unable to grow in the presence of low oxygen atmospheres or in a hydrogen atmosphere and are described as aerobic heterotrophs.

The predominant bacterium is a gram negative rod (0.7-1.4 micrometers) mobile by means of a single polar flagellum approximately three times the body length. Optimum growth occurs at 30°C with limitations at 5-42°C. Metabolism is respiratory, never fermentative. The optimum pH range for the bacteria is 7.0-8.5. Nitrates and nitrites are not reduced and H_2S is not produced; all of these factors are critical to both the treatment process and the structural features of the plant.

The bacteria oxidize free and complexed cyanides to carbonate and ammonia and metals are absorbed, ingested and precipitated as follows:

$$(1)\quad M_xCN_y + 4H_2O + O_2 \xrightarrow{\text{Bacterium}} \text{M-biofilm} + 2HCO_3^- + 2NH_3$$

The order of rate of degradation increases from Zn, Ni, Cu to Fe for metal complexed cyanides in lime with the complex stability sequence.

Iron cyanides have been shown to be degraded as well as adsorbed at rates of degradation exceeding those previously reported.

Thiocyanate degradation is similar and rapid and occurs in the pH range 7.0 - 8.5 also which is higher than the range reported in the literature.

$$(2)\quad 2SCN^- + 5O_2 + 4H_2O \xrightarrow{\text{Bacterium}} SO_4^{-2} + HCO_3 + NH_3$$

Following the degradation of thiocyanate, cyanides and metals removal through adsorption, the NH_3 must be removed. This is achieved in the nitrification stage by means of a common pair of anaerobic autotrophic bacteria (using inorganic carbon as sole source of carbon and inorganic materials as their sole nutrient source.)

Degradation and nitrification of ammonia are similar to that in activated sludge nitrification plants at the end of more modern sewage treatment plants.

$$(3)\quad 2NH_4^+ + 3O_2 \xrightarrow{\text{Bacterium}} 2NO_2^- + 4H^+ + H_2O$$

$$(4)\quad 2NO_2^- + O_2 \xrightarrow{\text{Bacterium}} 2NO_3^-$$

Ammonia is oxidized to nitrite slowly and then rapidly to nitrate. According to WHITLOCK & MUDDER (1984) the two microbial flora in the degradation stage and nitrification stage are normally non-competitive and are limited by the change in thiocyanate/cyanate concentrations.

Thiocyanate and cyanide are nutrients for the degradation stage bacteria and are toxic to the nitrifying bacteria. Ammonia acts as a nutrient for the nutrifiers and along with diminishing food source may act to control competition from cyanide degrading bacteria. An upset in the effectiveness of cyanide degradation would adversely affect the nitrificaiton stage and recovery of the nitrifying bacteria is several times slower than recovery for cyanide degraders. Hence the rate limiting factor incorporated into the plant design is based on the slower recovery rate of the nitrifiers. Reaction rates for thiocyanate, cyanide and ammonia are usually zero order down to low concentrations.

This means that the process is divided basically into two sections - the first to degrade cyanide and thiocyanate and adsorb and metabolize metals - the second to nitrify the ammonia byproduct.

TREATMENT PLANT DESIGN

Testwork by MUDDER & WHITLOCK (1981) showed that an activated sludge will work, but even with aeration periods ranging from 6 - 24 hours, the system fails after about 60 days due to metal overload.

The system employed uses 48 rotating biological contactors (RBCs) followed by clarification and pressure sand filters with dual media beds.

PILOT PLANT RBC RESULTS AT HOMESTAKE, LEAD, SOUTH DAKOTA (ppm)

	CNS	CN_T	Method-C Cyanide	Ammonia	Copper

WALKER PROCESS

Dedicated to the Water & Wastewater Industry

BIOSPIRAL

ROTATING BIOLOGICAL CONTACTOR

2620

INTRODUCTION

Rotating Biological Contactor systems (RBC's) are widely applied in municipal and industrial wastewater treatment where a high degree of BOD and NH_3 removal is required. RBC technology is based on the "dynamic" fixed film principle in which media, mounted on a slowly rotating horizontal shaft, is alternately submerged in a tank of wastewater and then exposed to the atmosphere. Microorganisms attach themselves to the media where they oxidize organic pollutants contained in the wastewater.

RBC systems offer several significant advantages over other types of secondary treatment processes including

- **Low energy requirements**
- **Low space requirements**
- **Operational simplicity**
- **Low maintenance requirements**
- **Low system headloss**
- **High treatment efficiency**
- **Good resistance to shock loads**

RBC systems are applied in a variety of configurations including new plant construction, trickling filter or activated sludge plant upgrades and polishing for municipal treatment systems. They have also been used in the petrochemical, textile, food and beverage industries and others. RBC systems available include smaller diameter treatment modules in steel tanks for commercial treatment applications to multiple full-size shafts for large treatment plants.

RBC systems are a proven, effective treatment alternative for biological reduction of organic pollutants.

The Walker Process BioSpiral RBC provides the mechanical and structural reliability we have been known for in the wastewater field since 1946. Our BioSpiral combines the largest structural components standardly available with a superior design to produce a rugged RBC capable of the sustained performance you require in your plant. The Walker Process engineering staff will provide the designer with necessary assistance in developing the most efficiently sized RBC system for his particular treatment requirements. Our unique media arrangement provides the capability to custom design a system for any application.

The following pages will introduce you to our BioSpiral RBC and highlight the beneficial features available with the BioSpiral. For further information please contact your local Sales Representative or Walker Process in Austin, Minnesota or Aurora, Illinois.

2621

GENERAL DESCRIPTION

The Walker Process BioSpiral utilizes a patented media and manufacturing process which provides a configuration that limits stresses in the polyethylene media to very low levels and provides a short flow path for air and water exchange through the media. The media is thermally welded in 36 inch wide modules in a continuous spiral wrapping process to produce a monolithic, self-supporting structure. This fabrication technique eliminates the need for media supports or torque transmitting devices which require periodic maintenance and produce localized stress concentrations in the media. The short flow path and open media construction also produce improved media scour and higher dissolved oxygen levels in the wastewater.

RBC's, like any major item of wastewater equipment, must be built to last to maintain the successful performance of the plant. Competent manufacturers design their RBC's to provide reliable performance and longevity based on applicable codes. Walker Process was the first to design its RBC shaft based on the fatigue provisions of The American Welding Society Structural Steel Welding Code D1.1, Chapter 10.

This design code is now widely recognized in the industry and by the USEPA as a necessary technique to assure reliable structural designs. Low shaft and media stress levels, good quality control and competent design are built into the BioSpiral to assure a design life of over 20 years. Fabrication is strictly controlled with our in-house Q.A. program to assure that the quality designed for is built into each BioSpiral. Pipe for the main shaft is purchased from the mill fully tested, meeting the requirements of API5L. Stub end machining, welding and media fabrication are checked at each step in the manufacturing process. Design stress values have been fully confirmed with full-scale testing.

BioSpiral standard shafts are approximately 26 feet long and 11 feet 10 inches in diameter, with either standard density media modules for 100,000 $ft.^2$ or high density media modules for 150,000 $ft.^2$ or more of effective surface area. The spiral media module design incorporated into the BioSpiral allows custom fabrication of shafts for specific applications. Process loadings, space availability, or existing structures may require special areas or special media diameters. The BioSpiral can be fabricated to any diameter between 6 and 12 feet and any shaft length to 26 feet, using from one to eight modules. The following pages further discuss the advantages available with the BioSpiral.

FEATURES

The main shaft is a 30 inch diameter, 3/4 inch wall pipe section with one-piece cast steel stub ends. The stub ends are first machined over their full surface to remove all surface imperfections and then tested to locate and eliminate any casting flaws. With our unique media design, no welded media attachment collars or clips are necessary on the main shaft. This eliminates the potential for stress concentrations which exist at such discontinuous attachments. The BioSpiral provides the largest shaft section modulus available in the industry at 492 in.^{3}. This, combined with good welding design, produces low stress levels to insure long shaft life.

Bearings provided with the BioSpiral are also the largest available in the industry at 7 inch diameter on full size shafts. This results in lower unit loadings and longer bearing life. Bearings are self-aligning, tapered roller pillow block units with a minimum AFBMA B_{10} life rating of over 200,000 hours at normal rotational speeds and loads. Fixed bearings are used at the drive end with expansion bearings on the idle end. The BioSpiral is manufactured and shipped with bearings in place permitting offloading directly to the anchorage.

Media is vacuum formed, high density polyethylene continuously wound and thermally welded within itself to produce a self-supporting structure. Every point of contact in the media structure is welded to assure media strength. Tested weld strength exceeds all design operating loads by a factor of 10 or more. A two-part system provides positive attachment of the media to the main shaft with the use of stainless steel straps, and an epoxy adhesive. Media is stabilized with carbon black to resist exposure to ultraviolet degradation and maintain tensile strength. The short air-water flow path and open construction of the media has been shown to provide good media scouring action and somewhat higher dissolved oxygen levels than produced with a more closed type of media.

Direct mechanical drive is used with a triple reduction helical torque arm reducer mounted directly on the stub end extension. Positive mechanical drive has been shown to be the most reliable and energy efficient, RBC drive system available. The shaft mounted drive is a significant improvement over the chain and sprocket designs which require an oil bath chain guard submerged in the tank. The reducer is driven through V-belts by a five horsepower motor to produce the desired rotational speed. Although not normally necessary, speed variation can be obtained by changing sheaves, a more economical and trouble free method than using variable speed drives.

Fiberglass enclosures can be provided for protection of the process against weather and for temperature and odor control. Enclosures can be provided which also enclose the RBC drive, if desired. BioSpiral enclosures consist of free standing arch sections with tongue and groove joints requiring no bolting for ease of assembly. Joint design allows for air infiltration to provide oxygen for the biological process. Enclosures are designed for normal wind or snow and live loads and are provided with access doors and inspection ports.

DESIGN CONSIDERATIONS

Proper evaluation and application of an RBC system requires careful consideration of many factors that affect system sizing and performance. The first step in properly designing a system is to determine the basic wastewater characteristics and effluent requirements. Design can be completed with the following parameters:

INFLUENT TO RBC SYSTEM

Flow, daily average	_____	GPD
Flow, peak two hour duration	_____	GPD
Flow, minimum	_____	GPD
Total BOD_5	_____	mg/l
Soluble BOD_5	_____	mg/l
TSS	_____	mg/l
*TKN	_____	mg/l
*NH_3N	_____	mg/l
*Alkalinity ($CaCO_3$)	_____	mg/l
Temperature/summer	_____	°F
Temperature/winter	_____	°F
pH	_____	

EFFLUENT

Total BOD_5	_____	mg/l
*NH_3N/summer	_____	mg/l
*NH_3N/winter	_____	mg/l

In evaluating these parameters, the designer will also rationally apply loading values, temperature corrections, staging and other design considerations to arrive at the proper RBC system size and arrangement.

For purposes of allowing the designer to gain a rough approximation of the RBC system for his application, Walker Process has developed sizing charts for determining surface area required for various BOD_5 and NH_3N loadings. These are preliminary design values, of course, and the designer should contact his local Walker Process Sales Representative for specific information. Walker Process engineers will assist the designer and will perform a careful analysis of each particular application and provide specific information suitable for that application. Proper shaft arrangement, staging and exact design application can significantly affect the surface area selected from the charts. Consult Walker Process for flows or influent loadings beyond the limits of the curves.

50	0.79
55	1.00

TEMPERATURE CORRECTION TABLE

45	0.73
50	0.87
55	1.00

FOOTNOTES

1. Charts are based on 100 GPD/capita.
2. Temperature correction must be applied to values from charts below temperatures of 55° F.
3. Effluent total BOD is 30 mg/l with soluble BOD of 15 mg/l.
4. Normally, and for purposes of approximation, standard density media is applied for BOD removal and high density media for NH_3H removal.
5. Standard shafts normally utilize 100,000 ft.² (standard density) and 150,000 ft.² (high density) maximum media surface area per shaft. For total surface areas beyond these values apply multiple shafts.
6. NH_3N removal chart assumes SBOD level is reduced to about 15 mg/l.
7. For purposes of approximation, add surface areas obtained from the charts for combined BOD and NH_3N removal. In actual practice this is generally conservative.
8. Flowrates may have to be adjusted prior to entering the charts if the peak to average ratio exceeds 2.5.
9. Consult Walker Process for values not listed in the charts, for specific design applications, and staging arrangements.

EXAMPLES

Example 1: (BOD removal only)

Flow = 0.28 MGD

SBOD = 100 mg/l (RBC influent)

TBOD = 30 mg/l (effluent)

Winter temperature = 45° F

From chart; 140,000 ft.² is required applying temperature correction;

$$\frac{140,000}{0.73} = 191,800 \text{ ft.}^2$$

Use two standard density shafts @ 100,000 ft.² each; 200,000 ft.² total; two parallel tanks.

Example 2: (BOD and NH_3N removal)

Flow = 0.45 MGD

SBOD = 50 mg/l (RBC influent)

NH_3N = 12 mg/l

TBOD = 30 mg/l (effluent)

NH_3N = 4 mg/l

Winter temperature = 48° F

From charts and applying correction factors;

For BOD removal; $\frac{130,000}{0.73}$ = 178,000 ft.² required

For NH_3N removal; $\frac{180,000}{0.56}$ = 321,000 ft.² required

Use two standard density shafts @ 100,000 ft.² each; two high density shafts @ 150,000 ft.² each; 500,000 ft.² total; two parallel tanks.

In addition to BioSpiral Rotating Biological Contactors, Walker Process supplies a full line of water and wastewater components and systems including clarifiers, anaerobic digestion equipment, ClariCone Reactor Clarifiers, Filters and much more.

Feed to the plant consists of a proportioned blend of tailings impoundment decant water and mine water the proportion monitored and regulated by an on-line automated thiocyanate monitor developed in-house. The blended water is regulated to control the incoming nutrient stream concentration and temperature of the blend. Minewater is at an almost constant 26°C, so the waters are blended to average 70:30 mine to tailings water in winter and 50:50 in summer still keeping within the bacterial limits.

Much of the nutrient requirement is in the water already although phosphorous for energy and carbonate as an essential source of inorganic carbon are supplemented by chemical addition in the form of phosphoric acid and soda ash.

Provision is made to add ferric chloride and polymer for additional metals removal and for clarification as needed.

The 48 RBC's are set in two identical mirror image arrangements of 24 each. Feed flows perpendicularly to the disc with five discs per train.

In general, the first two discs per train remove CNS^- and CN^- and accumulate metals while the remaining three are for nitrification.

Each disc is fitted with aeration headers and load cells for supplemental aeration and biofilm thickness monitoring.

Discs are about 40% submerged and rotate at variable speeds of 0.5-1.5 RPM driven by reversible drives. Physical dimensions of each disc is 3.65 mØ and 7.6 m long constructed of corrugated plastic media on a central shaft to present a surface area of 9.290 m^2 (100,000 ft^3) to 13,935 m^2 (150,000 ft^3) depending on the density of the media.

The first two cyanide and thiocyanate degradation discs are low density and the last three are high density to accommodate the weight of the biofilm. Each RBC is individually housed in its own insulated fiberglass cover as illustrated in the brochure. The bacterial biomass attached to the RBC should average 18,000 Kg (20 net tons).

CYANIDE DETERMINATIONS

Considering the complexity and variability of wastewater measurement, reliable means of reproducibly analyzing the flows were found essential especially at trace levels.

HOMESTAKE MINING COMPANY found that the EPA total cyanide method substituting H_3PO_4 for sulfuric acid works reliably for total cyanide including iron cyanides. The

FIGURE 2

BIOLOGICAL DEGRADATION OF AMMONIA, CYANIDE, AND THIOCYANATE

SOURCE: WHITLOCK & MUDDER (1984)

ASTM Method C was found satisfactory for available cyanide in Homestake's particular wastewater. Method C measures total cyanide less iron cyanide. It was found that Method-C cyanide measurement avoids many of the interferences which complicate the total cyanide method.

TOXICITY TESTING

WHITLOCK & MUDDER (1984) stressed that treatment methods which rely solely on chemical analyses of the treated effluent may result in unexpected toxicity due to the sporadic presence of an overlooked toxic contaminant, or due to synergistic/antagonistic effects.

Homestake has constructed an on-line bioassay facility to test the effluent stream using trout, daphnia and macroinvertebrates collected from the actual receiving stream.

Through use of the on-line bioassay laboratory Homestake Mining Company has been able to develop information on meaningful site specific water criteria to determine the effect of water on that particular stream.

WHITLOCK & MUDDER (1984) have made a major contribution both in developing a biological process to treat a toxic stream, but also in developing the concept of an on-line bioassay laboratory to obtain a much better picture of the usefulness and effectiveness of the treatment program.

BIOLOGICAL PROCESSES FOR CYANIDE REMOVAL (TENTATIVE)

Advantages

1) Bacterial processes remove chemical species from water while adding very little back in the way of chemical species unlike chemical treatment processes.

2) The acclimated bacteria serve to remove all the main contaminants from the stream, albeit in two separate bacterial processes in series. These include CN_T, CN^-, Cu, Ph, Zn, As, and NH_3.

3) Once established the cost of chemical additions will be minimal. (Data on amount and cost of H_3PO_4 and Na_2CO_3 addition was not yet released.

4) This process is a bold pioneering work and represents real progress. Biological processes akin to this are routinely used in several other industries and the RBC equipment is already available as a standard item if not already completely "debugged."

5) Minimal pH adjustments up or down are required.

Disadvantages

1) The capital cost of the plant appears to be high although the inventors claim that it was the least costly of the available process combinations able to achieve the same levels.

2) The two step process is vulnerable in that if the CN degradation step should upset, the second denitrification step will be interfered with too and it takes longer to be restored.

3) General applicability of the biological processes may not be possible in cold climates. The Homestake Mining Co. minewater at a constant 26°C (79°F) enables the mixture of mine and tailings effluent to be within the optimum temperature range year round.

   Biological processes generally slow down at lower temperatures and for most operations which do not have a source of heated effluent, winter temperatures of solutions will drop below the 10-11°C at which point the process will slow down to be less effective, even though WHITLOCK & MUDDER claim the bacteria function down to 5°C.

4) Being biological in nature the processes are subject to upsets. Discharging inadequately treated water to the creek for one 24 hour period will likely do as much damage as for a year long period. A means of testing water quality continuously and provision for returning it to the tailings dam when it does not meet discharge criteria is essential.

5) Long and short term toxicological characteristics of the effluent product have not yet been proven.

6) Probably it would be difficult or impossible to treat tailings pulp directly for cyanide degradation in RBCs because of the high solids levels.

FeS DESTRUCTION OF CYANIDES

The use of freshly made ferrous sulfide in the presence of a reducing agent i.e., excess ferrous sulfate for cyanide removal is described in the following patent by KUIT and BABCOCK (1981) of COMINCO LTD. The CON Mine cyanide treatment process is a combination of chemical treatment and natural degradation in a large shallow pond.

CYANIDE

This process is employed at COMINCO's Con Mine in Yellowknife Northwest Territories which was visited by RANDOL in June 1984 and is the subject of a trip report. Unfortunately, at the time of the visit the personnel who are knowledgeable about the process were on summer vacation and operating parameters and performance data were not available on site. Composition of the CON Mine influent solution composition as well as their tailings pond decant and permit limits are included in the paper by SCOTT (1984) inserted above.

Sponsors interested in gaining details of how this process works in practice may get in touch with the following people:

In practice at the Con Mine, tailings are discharged at the mill end of a very large shallow tailings impoundment using the downstream impoundment principle. Solution is decanted and flows to the impoundment overflow weir at the far end where it is discharged to the Great Slave Lake via a creek.

The tailings decant is treated by addition of ferrous sulfate and sodium sulfide directly to the tailings pond in two steps.

1) Ferrous sulfate and sodium sulfide are added near the point of discharge from the mill. At this point, the pH is 10.5 - 11.0.

2) Ferrous sulfate and lime are spread into the tailings pond at the discharge end into the decant solution close to the decant overflow weir. The reagents are delivered in bags which are spread over the solution surface from a mobile raft.

Total tailings from the Con Mine are generated at the rate of 750 tpd but after a sand/slime splip for backfill, only 400 stpd slimes reach the tailings pond at 25% solids, i.e., 1,100 m^3/d (1,200 stpd) water. Because of the 6 months frozen season, tailings

[57] **ABSTRACT**

A method is disclosed for removal of free and complex cyanides from water-containing industrial effluents and wastes by treatment with insoluble solid iron sulfides at a pH in the range of about 7.0 to 8.5. The insoluble solid iron sulfides can be chemically prepared prior to treatment or prepared in situ, usually of a particle size smaller than about 5μ, or supplied in the form of naturally occurring iron sulfides such as pyrrhotite or pyrite having a particle size smaller than about 300μ, preferably smaller than about 150μ. The weight ratio of iron sulfide to total cyanide in the effluent is greater than 2:1, preferably greater than about 5:1 for prepared iron sulfides and greater than about 100:1 for mineral sulfides. The presence of a reducing agent such as ferrous ions or sodium sulfite to maintain a non-oxidizing environment during treatment enhances removal of cyanide.

22 Claims, No Drawings

PROCESS FOR THE REMOVAL OF CYANIDES FROM EFFLUENT

BACKGROUND OF THE INVENTION

This invention relates to the removal of cyanide from effluents and wastes and, more particularly, relates to a method for the removal of free and combined dissolved cyanides from aqueous industrial effluents and wastes.

Due to increasingly stringent requirements for the disposal of noxious materials in waste waters and effluents from industrial processes, considerable effort has been expended, especially during the last ten years, to detoxify effluents that contain cyanides. As a result, many methods are reported in the literature that disclose the removal of free and combined cyanides from such effluents. These methods include oxidation of cyanide by treatment with chlorine, hypochlorite or ozone, treatment with an aldehyde, treatment with activated carbon or silica, removal as precipitated metal cyanides, treatment with fly ash or flue gas, and removal by irradiation, chelating, ion exchange or heating. However, in practice, most of the reported methods do not achieve the removal of cyanides and complex cyanides to levels that satisfy the requirements for safe disposal of aqueous effluents, while many methods are economically unattractive for the removal of small concentrations of cyanides from large quantities of effluent. Moreover, most methods are unsuitable to remove cyanides from slurries and solids such as flotation tailings.

We have now discovered that free cyanide as well as combined cyanides can be effectively and economically removed from effluents by treating the effluents with iron sulfides.

In the flotation concentration of mineral values in ores, cyanide ions are often used to depress certain sulfides such as, for example, iron sulfides in the concentration of lead sulfide. The depression of sulfides with cyanide ions is usually carried out at pH values of from 8 to 12.

Several methods have been disclosed that relate to the treatment of effluents with iron sulfides. According to U.S. Pat. No. 3,294,680, there is disclosed a method for reducing and removing chromate from solution by contacting the solution with a mass of hard metal sulfide, such as iron sulfide granules, at a pH of about 7.5.

According to U.S. Pat. No. 3,740,331, there is disclosed a method for the removal of heavy metal pollutant ions in a sulfide precipitation wherein sulfide ion and a heavy metal ion, which form a sulfide having a higher equilibrium sulfide ion concentration than the sulfide of the heavy metal pollutant, are added to the solution. In U.S. Pat. No. 3,901,802 there is disclosed a process for extracting heavy metal ions from solution wherein solution is contacted with an insoluble mixed salt of iron sulfide and barium sulfate containing a surplus of sulfide ions. According to U.S. Pat. No. 4,102,784, heavy metal pollutant ions are precipitated from solution by adding a slurry of large particle size ferrous sulfide precipitate to the solution in the presence of a polyelectrolyte to form a colloid-free metal ion precipitate. The foregoing methods are strictly related to the removal of heavy metal ions.

In a Technical Bulletin issued by the Permutit Co., on the Sulfex (Trade Mark) Heavy Metals Waste Treatment Process, it is stated that the process for removal of heavy metals with freshly precipitated iron sulfides at pH 8-9 is a heavy metal removal system, and that any

cyanides must be oxidized in a pretreatment step. According to Japanese Kokai No. 53 101 846, which issued on Sept. 5, 1978, there is disclosed a method for the inhibition of corrosion of waste water treatment apparatus in which ferrous ions are added to waste water that contains hydrogen sulfide, ammonia and cyanide corrosion inhibitor. The water is filtered to remove iron sulfide and then treated in a stripper.

STATEMENT OF INVENTION

We have now discovered that free cyanide ions and complex cyanide ions can be effectively and economically removed from effluents and wastes by treatment with iron sulfides under carefully controlled conditions.

Accordingly, there is provided a method for the removal of dissolved free and complex cyanides from water-containing effluent which comprises controlling the pH of said effluent in a range of about 7.0 to 8.5 and treating said effluent with an effective amount of an insoluble iron sulfide chosen from at least one of ferrous sulfide and ferric sulfide having particle sizes smaller than about 300μ for a period of time of at least about 5 minutes to remove said dissolved free and complex cyanides to a desired level, said effective amount being sufficient to give a weight ratio of said iron sulfide to total cyanide in said effluent of greater than 2:1.

DESCRIPTION OF PREFERRED EMBODIMENTS

The invention will now be described in detail. Effluents that may be treated according to the method of the invention are aqueous solutions, suspensions and slurries that are encountered in the metallurgical and metal processing industries. Such effluents comprise, for example, tailings and solutions from flotation processes for concentrating metal values in ores and electro-plating waste solutions which contain cyanides as free cyanide ions and/or metal cyanide complex ions of such metals as iron, copper, nickel and zinc. Effluents may be treated as such or may be pretreated for removal of at least a portion of the solids such as by settling or thickening and decantation, or filtration, with or without the use of flocculants or filter aids.

Effluent is treated with solid iron sufides under controlled conditions whereby a major portion of the free and complex cyanides is removed from the effluent. Without being bound by theoretical considerations, the removal is believed to be mostly due to adsorption of free and complex cyanides on the surface of the insoluble solid iron sulfide particles. The treatment is conducted by contacting an effective amount of finely divided solid iron sulfides with effluent for a period of time sufficient to reduce the cyanide content of the effluent. The contacting is performed by using known methods for obtaining intimate contact between effluent and iron sulfides. For example, effluent is agitated with solid iron sulfides, or effluent is agitated with a slurry of solid iron sulfides, or effluent is percolated through a body containing solid iron sulfides. The contacting by agitation with iron sulfide may be performed in a single stage, or may be performed in two or more stages in co-current or counter-current fashion.

Suitable iron sulfides are ferrous sulfide and ferric sulfide which may be used in the form of prepared compounds, i.e. chemically prepared iron sulfides, either as purchased or freshly prepared prior to the treatment of effluent or prepared in situ, or in the form of

naturally occurring mineral iron sulfides such as pyrrhotite and pyrite. Freshly prepared iron sulfides are made by conventional methods, while iron sulfides prepared in situ are preferably obtained by adding to the effluent a predetermined amount of ferrous sulfate or ferric sulfate and a stoichiometric amount of sodium sulfide or other suitable soluble sulfide that forms ferrous sulfide or ferric sulfide with the ferrous sulfate or ferric sulfate, respectively. The mineral iron sulfides are preferably used in the form of tailings or concentrates which contain at least one of pyrrhotite and pyrite.

The degree of cyanide removal is a direct function of the mass to surface area ratio of the iron sulfides. The lower the ratio, i.e. the finer the size of the iron sulfides, the more efficient and complete will be the cyanide removal. Prepared iron sulfides have particle sizes that are usually smaller than about 5μ (microns). Mineral iron sulfides in the form of tailings or concentrates are usually also finely divided, i.e. have particle sizes that are smaller than about 300μ, usually smaller than 150μ. If desired, coarse mineral sulfides may be subjected to a particle size reduction operation. A size reduction to particle sizes smaller than at least about 300μ, preferably smaller than about 150μ, is advantageous.

The choice of whether to use prepared or mineral iron sulfides depends on the manner in which effluent is contacted with iron sulfides, as well as on economic considerations. Mineral sulfides may be advantageously used where they are readily available. Because mineral iron sulfides have generally larger particle sizes than prepared sulfides, the use of mineral sulfides in the form of tailings and concentrates requires larger amounts and longer contact periods to attain the same degree of cyanide removal than the use of prepared sulfides. The lower efficiency of mineral sulfides may also be due to the presence of aged surface areas and residual flotation agents. The effectiveness of mineral iron sulfides in the process of the invention may be increased by subjecting the sulfides to milling whereby not only particle sizes are reduced but also fresh surface areas are exposed.

Mineral iron sulfides are advantageously used when effluent is treated by percolating effluent through a body of iron sulfides. The body of iron sulfides consists of a column or bed of finely divided solid mineral iron sulfides having particle sizes generally larger than about 44μ, preferably in the range of about 44 to 300μ, most preferably in the range of about 44 to 150μ. Too large a content of mineral sulfide particles smaller than about 44μ causes too rapid a decrease in the effectiveness of the percolation body due to plugging of the interstices in the body and a consequent diminishing of the percolation rate, while particles larger than 300μ have a high mass to surface area ratio which is less effective than a lower ratio. The method of contacting by percolation is suitable when treating aqueous effluents that are substantially free of solids or have a low solids content. It is reiterated that effluents may be treated for removal of at least a portion of contained solids prior to being subjected to percolation.

Prepared iron sulfides are used when cyanide levels must be reduced to very low levels in effluents that contain solids and in cases where mineral sulfides re not available or are uneconomical to use. Ferrous sulfide and ferric sulfide may be used singly or as a mixture. As stated hereinabove, prepared iron sulfides can be readily obtained by purchase or can be prepared prior to treatment of effluent or in situ. Preferably, iron sulfides are prepared in aqueous solution by reacting ferrous sulfate and/or ferric sulfate, or other suitable ferrous and/or ferric salt, with a soluble sulfide causing precipitation of finely divided solid ferrous and/or ferric sulfide. The resulting reaction mixture is subsequently added to the effluent in the form of a slurry or suspension either batchwise in a predetermined amount or in continuous or semi-continuous fashion at a predetermined rate. Alternatively, iron sulfides are prepared in situ by adding predetermined amounts of ferrous and/or ferric sulfate or other suitable ferrous and/or ferric salts and a suitable soluble sulfide causing precipitation of ferrous and/or ferric sulfide. The effluent and added or in situ-prepared iron sulfides are thoroughly agitated to ensure intimate contact between effluent and iron sulfide particles. After a suitable contact time, the mixture may be separated into treated effluent and iron sulfide components. The iron sulfides may be impounded or, if desired, a portion of the iron sulfides may be recycled after separation from treated effluent for treatment of further amounts of effluent.

The amount of prepared or mineral sulfides to be used depends on the physical characteristics of the effluent, the amounts and nature of the cyanides in the effluent, the origin and nature of the iron sulfides and, in the case of mineral sulfides, on the amount of iron sulfides present in the concentrate or tailings employed.

Generally, the amount of iron sulfides must be used or added in an effective amount, i.e., an amount that is at least sufficient to remove dissolved free and complex cyanides from the effluent to the desired level. Preferably, iron sulfides are used in excess. The excess may be expressed as the weight ratio of iron sulfides, i.e. ferrous sulfide and/or ferric sulfide, to the total cyanide content of the effluent, denoted hereinafter as the FeS/CN ratio. For percolation, this ratio will, of course, be very high, such as 100:1, and as high as 10^6:1, while for agitating iron sulfides with effluent the ratio should be at least about 2:1, i.e. provide a 100% excess of sulfides. When using prepared iron sulfides, the ratio is preferably in the range of about 5:1 to 20:1, while when using mineral sulfides, the ratio is preferably at least 100:1.

The pH during contacting of effluent with iron sulfides is critical and must be carefuly controlled. The pH is to be controlled in the range of about 7.0 to 8.5. Below a pH of about 7, hydrogen cyanide is liberated and cyanide complexes are not removed effectively. At a pH above about 8.5, cyanide removal is incomplete due to increased competition of cyanide and complex cyanide ions with hydroxyl ions for adsorption on the iron sulfide surfaces. The value of the pH is preferably maintained in the range of about 7 to 8, and most preferably at a value of about 7.5 which results in optimum removal of free and complex cyanides. We have found that cyanide ions are most strongly adsorbed in the pH range of 7 to 8 and that, for example, cuprocyanide is dissociated by ferrous sulfide and pyrrhotite leaving the cyanide strongly bound to the adsorbent. Copper is removed from solution by precipitation. The pH of the effluent is adjusted to a pH in the range of about 7 to 8, preferably to a value of about 7.5, prior to or during contacting with iron sulfides and the pH is maintained in this range during the contacting step. The adjusting and maintaining of the pH in the preferred range is accomplished by adding either an acid, such as dilute sulfuric acid, or an alkali, such as sodium hydroxide or lime, as required.

Although the adsorption process is temperature dependent, the treatment of effluent is carried out at ambi-

ent temperatures using the effluent at the temperature at which it is obtained. The contacting is carried out over a period of time that is sufficient to reduce the cyanide content of the effluent to the desired level. Using prepared iron sulfides which have particle sizes smaller than 5μ, a contact time of at least 5 minutes is required to obtain removal of cyanides. When agitating effluent with prepared iron sulfides, the contact time is preferably in the range of about 15 to 180 minutes and, most preferably, in the range of 15 to 60 minutes. For mineral iron sulfides which have particle sizes in the range of 44 to 300μ, the contact time is preferably at least 30 minutes and most preferably in the range of about 30 minutes to 10 hours. When percolating effluent through a body of particulate iron sulfides, the contact time is preferably at least 30 minutes and is most preferably in the range of about 1 to 24 hours.

We have found that the presence of a reducing agent will further depress the amount of cyanide in solution. Suitable reducing agents, eg. ferrous ions and sodium sulfite, are added in a quantity to maintain a non-oxidizing environment. We have also found that in the case of high concentrations of the ferrocyanide complex in the effluent, the presence of free, i.e. excess, ferrous ions will cause precipitation of prussian blue-type compounds. Thus, the presence of added free ferrous ions further depresses the total cyanide content of the effluent. Free ferrous ions are added in the form of a suitable, soluble ferrous salt.

The invention will now be illustrated by means of the following non-limitative examples.

EXAMPLE 1

Effluent containing 38 mg/L total cyanide (T/CN), of which 14.4 mg/L was free CN and 23.6 mg/L was CN as cuprocyanide ($Cu(CN)_3^{2-}$), and having a pH of 9.5, was percolated through a bed of mixed pyrrhotite-pyrite concentrate. The concentrate was screened to particle sizes in the range of 44 to 74μ. The bed volume was 600 mL and the retention time of the effluent, which was pumped upwardly through the bed, was 30 minutes. 500 mL percolated effluent was collected which analyzed 0.08 mg/L T/CN and <0.01 mg/L as $Cu(CN)_3^{2-}$ and had a pH of 7.0.

EXAMPLE 2

The test of Example 1 was repeated but the concentrate was screened to remove particles smaller than 74μ. The percolated effluent had a pH of 7.5 and contained 0.68 mg/L T/CN and 0.05 mg/L CN as $Cu(CN)_3^{2-}$.

The tests of Examples 1 and 2 show that free and complex cyanides can be effectively removed from effluent by percolating through a bed of finely divided iron sulfides and that smaller particle sizes are more effective in the removal.

EXAMPLE 3

This example illustrates the removal of free and complex cyanides from tailings from a metallurgical operation by percolating tailings solution through a bed of pyrrhotite-pyrite concentrate. The tailings were settled and the decanted solution was filtered through a bed of diatomaceous earth to remove colloidal matter. The clarified solution contained 21 mg/L total cyanide (CN), 0.9 mg/L free CN, 10.3 mg/L CN as cuprocyanide ($Cu(CN)_3^{2-}$) and 9.8 mg/L CN as ferrocyanide ($Fe(CN)_6^{4-}$), and had a pH of 9.5. The percolation bed was prepared by wet screening the concentrate to remove particles smaller than 44μ and the remaining slurry was poured into a 4.6 cm diameter percolation column. After settling, the excess water was decanted. The final bed depth was 36 cm giving a bed volume of 600 mL. In a first test clarified solution was percolated at its natural pH of 9.5 and in a second test the solution was adjusted to pH 7.5 before being percolated.

The clarified solution was pumped upwardly through the bed at a rate of 3.75 mL/min. The treated effluent was collected in 600 mL portions over a period of 45 hours and analyzed. The retention time was one hour. The test results are given in Table I.

TABLE I

Test No	Cumulative volume of effluent in ml	pH	CN in treated effluent in mg/L: Total	free	as $Cu(CN)_3^{2-}$	as $Fe(CN)_6^{4-}$
1	600	9.5	0.24		0.01	0.45
	1200	9.5	2.0	0.4	0.06	1.54
	1800	9.5	5.1	1.1	0.04	4.0
	2400	9.5	6.3		0.01	6.5
	2700	9.5	8.5	0.4	0.01	8.1
2	300	7.5	0.60	0.18	0.03	0.39
	900	7.5	0.75	0.21	0.01	0.54
	1500	7.5	1.50	1.11	0.03	0.36
	2100	7.5	0.25		0.05	0.45
	2700	7.5	2.00	1.24	0.03	0.73

The results show free and complex cyanides can be effectively removed by percolation of effluent through a body of finely divided iron sulfides and that the removal is more effective at pH 7.5.

EXAMPLE 4

One liter of the effluent as used in Examples 1 and 2 was agitated for a period of 24 hours with 800 g of a mixed pyrite-pyrrhotite concentrate. The treated effluent had a pH of 7.5 and contained 0.08 mg/L total CN and <0.01 mg/L CN as $Cu(CN)_3^{2-}$. The FeS/CN weight ratio was 20000:1.

EXAMPLE 5

This example illustrates the removal of cyanide from tailings from a metallurgical operation by mixing tailings solution with varying amounts of an iron sulfide concentrate. The tailings were settled and one liter portions of the decanted solution containing 55 mg/L T/CN were mixed with concentrate for a period of 10 hours, while maintaining the pH at a value of 7.5. Samples were taken after 2, 4, 6 and 10 hours. The samples were filtered and analyzed for total cyanide (T/CN) content. The results are given in Table II.

TABLE II

Amount of Sulfides Concentrate in g	Weight Ratio iron sulfides to cyanides	T/CN in mg/L: 0 hr	2 hr	4 hr	6 hr	10 hr
250	4000:1	55	11	8	20	
667	10000:1	55	5.7	6.4	3.0	5.0
1500	23000:1	55	2.6	1.2	0.2	0.1
4000	62000:1	55	<0.2	1.5	1.5	

The results of the tests in Examples 4 and 5 show that cyanides can be effectively removed from effluent by agitating effluent with finely divided mineral iron sulfides at a pH of 7.5 using retention times of 2 to 19 hours at ratios of iron sulfides to total cyanides (FeS/CN) of 4000:1 to 62000:1.

EXAMPLE 6

400 mL portions of an effluent containing 100 mg/L T/CN, 16.7 mg/L free CN, 33.2 mg/L CN as $Cu(CN)_3^{2-}$ and 50 mg/L CN as $Fe(N)_6^{4-}$, and having a pH of 9.5, were adjusted to different pH values. The portions were each mixed with an amount of freshly prepared solid ferrous sulfide to give an iron sulfide to cyanide (FeS/CN) ratio of 8.33:1. The mixtures were each agitated for 15 minutes, a sample taken, agitated for a further 45 minutes, and a second sample taken. The samples were filtered through a 0.45μ filter and analyzed for cyanides. The results are given in Table III.

TABLE III

Retention time in min	Adjusted pH of Effluent	CN in Treated Effluent in mg/L			
		Total	Free	as $Cu(CN)_3^{2}$	as $Fe(CN)_6^{4}$
15	7.0	5.6	4.1	0.05	1.5
60	7.0	4.3	2.3	<0.02	2.0
15	8.0	4.7	1.1	0.06	3.6
60	8.0	1.9		<0.02	4.1
15	8.5	15	0	<0.02	15
60	8.5	9	0	<0.02	9
15	9.0	68	0	0.07	68
60	9.0	53	0	<0.02	53

It can be seen from the data given in Table III that a major portion of the cyanides can be removed from effluent by mixing with prepared ferrous sulfide at a pH in the range of 7.0 to 8.5 and that best results are obtained at a pH of from 7.0 to 8.0. A retention time of 60 minutes gives better results than one of 15 minutes. The data also show that copper and cuprocyanide are substantially removed from the effluent. The high figures for ferrocyanide at pH 9.0 indicate that ferrocyanide is formed and incompletely adsorbed on the sulfide.

EXAMPLE 7

This example illustrates that an excess of ferrous sulfide improves the removal of cyanide and that cyanide removal increases with increasing FeS/CN ratios. Portions of effluent containing 100 mg/L free CN at pH 7.5 were contacted with amounts of prepared ferrous sulfide to give predetermined FeS/CN weight ratios. The mixtures were agitated for 60 minutes, filtered and the treated effluent analyzed for total CN. The results are given in Table IV.

TABLE IV

Weight Ratio FeS/CN	Total CN in Treated Effluent in mg/L
1.0	38
3.0	23
4.0	12
5.0	3.5
6.3	0.48

EXAMPLE 8

Effluent containing 96 mg/L free CN and having a pH of 10.0 was adjusted to pH 7.5 using dilute sulfuric acid. Ferrous sulfide was prepared in the effluent by adding a solution of sodium sulfide and a solution containing ferrous sulfate in a stoichiometric amount to form ferrous sulfide in an amount to give a FeS/CN ratio in the effluent of 6.28:1. The mixture was agitated and samples taken after 15, 30, 60 and 180 minutes. The samples were filtered using a 0.45μ filter and the filtered samples were analyzed. The results are given in Table V.

TABLE V

Retention Time in min.	Treated Effluent Total CN in mg/L
15	1.9
30	1.0
60	0.48
180	0.84

The results show that free cyanide can be effectively removed by agitating effluent with ferrous sulfide prepared in situ for periods of time in the range of 15 to 180 minutes with best results obtained at 60 minutes.

EXAMPLE 9

Effluent containing 96 mg/L T/CN, 55 mg/L free CN and 41 mg/L CN as $Cu(CN)_3^{=}$ and having a pH of 9.5 was adjusted to pH 7.5 by adding the necessary amount of dilute sulfuric acid. Previously prepared ferrous sulfide having particle sizes of less than 5μ was added to the effluent in an amount to give a ratio of ferrous sulfide to total cyanide of 6.4:1. The mixture was agitated and samples taken after 15, 30, 60 and 180 minutes. The samples were filtered using a 0.45μ filter and the filtered samples were analyzed. The results are given in Table VI.

TABLE VI

Retention Time in min.	CN in Treated Effluent in mg/L	
	Total	as $Cu(CN)_3^{=}$
15	4.8	0.09
30	4.0	<0.01
60	1.2	<0.01
180	1.4	<0.01

The results show that free cyanide and cuprocyanide can be effectively removed by agitating effluent with prepared ferrous sulfide using retention times of from 15 to 180 minutes with best results obtained at 60 minutes retention.

EXAMPLE 10

Effluent containing 94 mg/L CN as $Fe(CN)_6^{4-}$ and having a pH of 9.5 was adjusted to pH 7.5. Prepared ferrous sulfide was added to the effluent in an amount sufficient to give a FeS/CN ratio of 6.4:1. The mixture was agitated and samples taken after 15, 30, 60 and 180 minutes. The samples were filtered through a 0.45μ filter and analyzed for T/CN. The results are given in Table VII.

TABLE VII

*All cyanide was adsorbed as the ferrocyanide complex.

The results shown in Table VII indicate that ferrocyanide can be substantially removed from effluent by treating the effluent with prepared ferrous sulfide at pH 7.5 and with agitation for a retention period of 15 to 60 minutes. At retention times appreciably longer than 60 minutes, the cyanide content of the treated effluent increases because of oxidation.

ent temperatures using the effluent at the temperature at which it is obtained. The contacting is carried out over a period of time that is sufficient to reduce the cyanide content of the effluent to the desired level. Using prepared iron sulfides which have particle sizes smaller than 5μ, a contact time of at least 5 minutes is required to obtain removal of cyanides. When agitating effluent with prepared iron sulfides, the contact time is preferably in the range of about 15 to 180 minutes and, most preferably, in the range of 15 to 60 minutes. For mineral iron sulfides which have particle sizes in the range of 44 to 300μ, the contact time is preferably at least 30 minutes and most preferably in the range of about 30 minutes to 10 hours. When percolating effluent through a body of particulate iron sulfides, the contact time is preferably at least 30 minutes and is most preferably in the range of about 1 to 24 hours.

We have found that the presence of a reducing agent will further depress the amount of cyanide in solution. Suitable reducing agents, eg. ferrous ions and sodium sulfite, are added in a quantity to maintain a non-oxidizing environment. We have also found that in the case of high concentrations of the ferrocyanide complex in the effluent, the presence of free, i.e. excess, ferrous ions will cause precipitation of prussian blue-type compounds. Thus, the presence of added free ferrous ions further depresses the total cyanide content of the effluent. Free ferrous ions are added in the form of a suitable, soluble ferrous salt.

The invention will now be illustrated by means of the following non-limitative examples.

EXAMPLE 1

Effluent containing 38 mg/L total cyanide (T/CN), of which 14.4 mg/L was free CN and 23.6 mg/L was CN as cuprocyanide ($Cu(CN)_3^{2-}$), and having a pH of 9.5, was percolated through a bed of mixed pyrrhotite-pyrite concentrate. The concentrate was screened to particle sizes in the range of 44 to 74μ. The bed volume was 600 mL and the retention time of the effluent, which was pumped upwardly through the bed, was 30 minutes. 500 mL percolated effluent was collected which analyzed 0.08 mg/L T/CN and <0.01 mg/L as $Cu(CN)_3^{2-}$ and had a pH of 7.0.

EXAMPLE 2

The test of Example 1 was repeated but the concentrate was screened to remove particles smaller than 74μ. The percolated effluent had a pH of 7.5 and contained 0.68 mg/L T/CN and 0.05 mg/L CN as $Cu(CN)_3^{2-}$.

The tests of Examples 1 and 2 show that free and complex cyanides can be effectively removed from effluent by percolating through a bed of finely divided iron sulfides and that smaller particle sizes are more effective in the removal.

EXAMPLE 3

This example illustrates the removal of free and complex cyanides from tailings from a metallurgical operation by percolating tailings solution through a bed of pyrrhotite-pyrite concentrate. The tailings were settled and the decanted solution was filtered through a bed of diatomaceous earth to remove colloidal matter. The clarified solution contained 21 mg/L total cyanide (CN), 0.9 mg/L free CN, 10.3 mg/L CN as cuprocyanide ($Cu(CN)_3^{2-}$) and 9.8 mg/L CN as ferrocyanide ($Fe(CN)_6^{4-}$), and had a pH of 9.5. The percolation bed was prepared by wet screening the concentrate to remove particles smaller than 44μ and the remaining slurry was poured into a 4.6 cm diameter percolation column. After settling, the excess water was decanted. The final bed depth was 36 cm giving a bed volume of 600 mL. In a first test clarified solution was percolated at its natural pH of 9.5 and in a second test the solution was adjusted to pH 7.5 before being percolated.

The clarified solution was pumped upwardly through the bed at a rate of 3.75 mL/min. The treated effluent was collected in 600 mL portions over a period of 45 hours and analyzed. The retention time was one hour. The test results are given in Table I.

TABLE I

2	300	7.5	0.60	0.18	0.03	0.39
	900	7.5	0.75	0.21	0.01	0.53
	1500	7.5	1.50	1.11	0.03	0.36
	2100	7.5	0.25	—	0.05	0.42
	2700	7.5	2.00	1.24	0.03	0.73

The results show free and complex cyanides can be effectively removed by percolation of effluent through a body of finely divided iron sulfides and that the removal is more effective at pH 7.5.

EXAMPLE 4

One liter of the effluent as used in Examples 1 and 2 was agitated for a period of 24 hours with 800 g of a mixed pyrite-pyrrhotite concentrate. The treated effluent had a pH of 7.5 and contained 0.08 mg/L total CN and <0.01 mg/L CN as $Cu(CN)_3^{2-}$. The FeS/CN weight ratio was 20000:1.

EXAMPLE 5

This example illustrates the removal of cyanide from tailings from a metallurgical operation by mixing tailings solution with varying amounts of an iron sulfide concentrate. The tailings were settled and one liter portions of the decanted solution containing 55 mg/L T/CN were mixed with concentrate for a period of 10 hours, while maintaining the pH at a value of 7.5. Samples were taken after 2, 4, 6 and 10 hours. The samples were filtered and analyzed for total cyanide (T/CN) content. The results are given in Table II.

TABLE II

Amount of Sulfides Concentrate in g	Weight Ratio iron sulfides to cyanides	T/CN in mg/L: 0 hr	2 hr	4 hr	6 hr	10 hr
250	4000:1	55	11	8	20	—
667	10000:1	55	5.2	6.4	3.0	5.0
1500	23000:1	55	2.6	1.2	0.2	0.1
4000	62000:1	55	<0.2	1.5	1.5	—

The results of the tests in Examples 4 and 5 show that cyanides can be effectively removed from effluent by agitating effluent with finely divided mineral iron sulfides at a pH of 7.5 using retention times of 2 to 10 hours, at ratios of iron sulfides to total cyanides (FeS/CN) of 4000:1 to 62000:1.

EXAMPLE 11

Two portions of effluent containing 35 mg/L total CN, 15.4 mg/L free CN, 4.1 mg/L CN as $Cu(CN)_3^{2-}$ and 15.5 mg/L CN as $FE(CN)_6^{4-}$ were adjusted to pH 7.5 and treated with prepared ferrous sulfide to yield varying FeS/Cn ratios and varying amounts of free ferrous ions were added. A third portion of effluent was similarly treated but no excess ferrous ions was present. The results are given in Table VIII.

TABLE VIII

Retention Time in min.	Ratio FeS/CN	Excess Fe^{2+} in mg/L	CN in Treated Effluent in mg/L Total	Free	$Cu(CN)_3^{2-}$	as $Fe(CN)_6^{4-}$
15	2	22.3	12	1.3	0.17	10.5
30	2	22.3	11	1.0	0.80	9.2
15	13.35	164.0	3.5	3.4	0.02	<0.1
30	13.35	164.0	2.2	2.1	0.02	<0.1
15	13.35	0	4.6	4.3	0.03	0.3
30	13.35	0	4.5	4.0	0.02	0.5

The data in Table VIII indicate that better removal of cyanides is obtained at high FeS/CN ratios and that the presence of free ferrous ions effectively reduces the cyanide content of the effluent.

EXAMPLE 12

Portions of a high cyanide containing effluent containing 560 mg/L total CN, 162 mg/L free CN, 51 mg/L CN as $Cu(CN)_3^{2-}$ and 347 mg/L CN as $Fe(CN)_6^{4-}$ were treated with prepared ferrous sulfide with and without the addition of excess ferrous ions. The FeS/CN ratio, effluent pH and retention times while agitating were varied. The results are given in Table IX.

TABLE IX

Retention Time in min	FeS/CN ratio	excess Fe^{2+} in g/l	pH	CN in Treated Effluent in mg/L Total	as $Cu(CN)_3^{2}$	as $Fe(CN)_6^{4-}$
60	2	0	7.5	156	<0.01	0.48
30	8.9	0	7.5	16	0.02	0.28
30	8.9	0	8.5	38	0.02	3.3
20	13.35	0	7.5	29	0.05	0.22
30	13.35	0	8.5	24	0.05	0.64
30	2	0.47	7.5	33	<0.01	0.22
30	5	1.18	7.5	31	<0.01	0.34
60	5	1.18	7.5	13	<0.01	

The tabulated results show that best results are obtained with retention times of 20 to 60 minutes at pH 7.5 using FeS/CN ratios of 5:1 to 15:1, that cuprocyanide and ferrocyanide are effectively removed from the effluent and that cyanide can be more effectively removed when free ferrous ions are present.

EXAMPLE 13

In a continuous operation for the treatment of cyanide containing effluent from a metallurgical operation, 91 L/min effluent, containing varying amounts of cyanides, was fed to an agitated reaction vessel. A slurry of ferrous sulfide was prepared in a separate vessel by mixing stoichiometric amounts of ferrous sulfate heptahydrate and sodium sulfide, both in aqueous solution. Slurry containing 54 g/L ferrous sulfide was continuously added to the reaction vessel in an amount sufficient to maintain the FeS/CN ratio as predetermined values. The pH of the mixture in the reaction vessel was maintained at 7.5 by adding an 18.6% solution of H_2SO_4 as required. During periods of the operation, excess free ferrous ions was added to the reaction vessel. The retention time of the effluent in the reaction vessel was 90 minutes. The discharging effluent was periodically sampled and the samples were filtered and analyzed. Operating parameters and analysis results are shown in Table X.

TABLE X

FeS in mg/L	FeS/CN weight ratio	Excess Fe^{2+} g/L	CN in effluent in mg/L free	$Cu(CN)_3^{2-}$	$Fe(CN)_6^{4-}$	CN in treated effluent in mg/L free	$Cu(CN)_3^{2-}$	$Fe(CN)_6^{4-}$
0.94	1.20	Nil	618.2	64.9	99.5	140.3	38.5	241.2
0.94	1.28	0.20	492.7	64.1	175.8	29.4	11.1	104.6
1.26	2.10	Nil	110.5	71.2	418.3	20.4	9.3	180.3
1.28	2.15	0.23	75.8	65.1	454.1	8.8	0.1	60.4
1.95	3.20	Nil	135.5	61.4	413.1	19.5	2.8	146.7
1.90	3.07	0.39	201.4	68.6	350.0	Nil	0.04	10.0

The data presented in Table X clearly demonstrate that in excess of 98% removal of T/CN was attained with an FeS/Cn weight ratio of about 3:1 and an excess of about 0.4 g/L ferrous ions.

EXAMPLE 14

One L effluent containing 100 mg/L T/CN and having a pH of 7.5 was agitated with an amount of prepared ferric sulfide sufficient to give a FeS/CN weight ratio of 10:1. The mixture was sampled after 15, 30 and 180 minutes retention and the samples, filtered and analyzed, were found to contain 23.0, 10.5 and 1.6 mg/L T/CN, respectively.

This example illustrates that cyanide can be effectively removed from effluent by treating with ferric sulfide.

EXAMPLE 15

One L portions of effluent containing 100 mg/L T/CN were treated with either 1 g prepared ferrous sulfide or ferric sulfide with and without a reducing agent. 120 mg SO_3 as sodium sulfite was used as reducing agent. The mixtures were periodically sampled and the samples were filtered and analyzed. The results are shown in Table XI.

TABLE XI

Retention Time in min	T/CN in mg/L Ferrous Sulfide without Reducing Agent	Ferrous Sulfide with Reducing Agent	Ferric Sulfide without Reducing Agent	Ferric Sulfide with Reducing Agent
15	0.76	0.20	23.0	21.0
30	0.32	0.20	10.5	9.3

TABLE XI-continued

Retention Time in min.	T/CN in mg/L			
	Ferrous Sulfide		Ferric Sulfide	
	without Reducing Agent	with Reducing Agent	without Reducing Agent	with Reducing Agent
60	0.30	<0.04	—	3.4
180	0.23	0.16	1.6	1.8

As can be seen from the results presented in Table XI, the presence of a sodium sulfite as a reducing agent further improves the removal of cyanide from effluent when the effluent is treated with ferrous sulfide. Little or no improvement was obtained in this example when effluent was treated with ferric sulfide.

It will be understood, of course, that modifications can be made in the embodiment of the invention described and illustrated herein without departing from the scope and purview of the invention as defined by the appended claims.

What we claim as new and desire to protect by Letters Patent of the United States is:

1. A method for the removal of dissolved free and complex cyanides from water-containing effluent which comprises controlling the pH of said effluent in a range of about 7.0 to 8.5 and contacting said effluent with an effective amount of an insoluble solid iron sulfide chosen from at least one of ferrous sulfide and ferric sulfide having particle sizes smaller than about 300μ for a period of time of at least about 5 minutes to remove said dissolved free and complex cyanides to a desired level, said effective amount being sufficient to give a weight ratio of said iron sulfide to total cyanide in said effluent of greater than about 2:1.

2. A method as claimed in claim 1, wherein the effluent contains cyanides of at least one of cyanide ions, complex cyanide ions of iron, copper, nickel and zinc, or mixtures thereof.

3. A method as claimed in claim 1, wherein said iron sulfide is prepared prior to treatment of effluent or in situ during treatment of effluent and has a particle size smaller than about 5μ.

4. A method as claimed in claim 3, wherein said weight ratio is in the range of about 5:1 to about 20:1.

5. A method as claimed in claim 4, wherein the effluent is contacted with the iron sulfide in a single stage, or in two or more co-current or counter-current stages.

6. A method as claimed in claim 3, 4 or 5, wherein the effluent and iron sulfide are agitated to ensure intimate contact between said effluent and iron sulfide particles and said pH is controlled in a range of about 7 to 8.

7. A method as claimed in claim 6, wherein iron sulfide is separated from effluent after contacting with said

iron sulfide and at least a portion of the separated iron sulfide is returned to said treatment.

8. A method as claimed in claim 3, 4 or 5, wherein said contacting is carried out for a period of time in the range of about 15 to about 180 minutes.

9. A method as claimed in claim 3, 4 or 5, wherein said contacting is carried out for a time in the range of about 15 to 60 minutes.

10. A method as claimed in claim 1, wherein the effluent is contacted with a particulate material chosen from concentrate and tailings, said material containing at least one mineral iron sulfide chosen from pyrrhotite and pyrite.

11. A method as claimed in claim 10, wherein said particulate material has particle size smaller than 150μ.

12. A method as claimed in claim 11, wherein said weight ratio is at least about 100:1.

13. A method as claimed in claim 1, wherein said contacting is carried out for a time in the range of about 30 minutes to 10 hours.

14. A method as claimed in claim 11, 12 or 13, wherein the effluent and iron sulfide are agitated to ensure intimate contact between said effluent and iron sulfide particles and said pH is controlled in a range of about 7 to 8.

15. A method as claimed in claim 1, wherein effluent is percolated at a pH in the range of about 7 to 8 through a particulate body containing mineral iron sulfide.

16. A method as claimed in claim 15, wherein said effluent is percolated through a particulate body of material chosen from concentrate and tailings containing at least one iron sulfide chosen from pyrrhotite and pyrite, and wherein the contact time of effluent with said body is at least about 30 minutes.

17. A method as claimed in claim 16, wherein said contact time is in the range of about one to 24 hours.

18. A method as claimed in claim 17, wherein said particulate body has particle sizes in the range of about 44 to 300μ.

19. A method as claimed in claim 15, 16 or 17, wherein said particulate body has particle sizes in the range of about 44 to 150μ.

20. A method as claimed in claim 15, 16 or 17, wherein said weight ratio is at least about 100:1.

21. A method as claimed in claim 1 or 2, wherein the effluent contains ferro-cyanide and wherein the effluent is treated with an excess of free ferrous ions.

22. A method as claimed in claim 1 or 2, wherein the iron sulfide is ferrous sulfide and the effluent is treated in the presence of sodium sulfite.

* * * * *

and solution are accumulated during the winter months. The liquid effluent decant is treated and discharged during the 6 warmer months.

The following rate of reagent consumption was reported for Con Mine which gives an idea of the amount of cyanide in the system and the reagents required to remove it:

Reagent Consumption at Con Mine, NWT
June 1984

Cyanide		1000	lbs	NaCN/day
Lime	1065	lbs		/day
$FeSO_4$	920	lbs	/day	
Na_2S	179	lbs	/day	
Zn dust		56.4	lbs	/day
Pb Acetate		14.0	lbs	/day

Notes

1) Because of the very large, shallow dam and because secondary treated is applied in summer only, there can be expected to be a significant natural cyanide degradation in the pond.

2) Because of the addition of sulfides and ferrous ions to the tailings dam, the decant water is unlikely to be suitable for recycling to the mill. In the NWT water is not in short supply.

3) Because of the sand/slime split and underground backfill, it is likely that minewater will contain some free cyanide.

CYANIDE DESTRUCTION BY PEROXIDE

Degradation of cyanide by hydrogen peroxide has been tested by several companies and recently installed on a commercial basis at the huge OK Tedi gold leaching operation in Papua, New Guinea.

The copper catalyzed hydrogen peroxide process is patented in the USA by DuPont and is known as the Kastone process. It is described by MATHRE & DEVRIES (1981) inserted below.

HOMESTAKE PILOT TESTS

MUDDER & WHITLOCK (1984) tested the DuPont Kastone process for the Homestake Lead effluent discussed above with thiocyanate and cyanide as well as copper and iron in relatively low levels, but still over effluent limits and 2-3 mg NH_3/l. It was found in a pilot plant test that this process provided the best solution to Homestake's treatment problem based on numerical and toxicological evaluations.

Suitability of DuPont Kastone Cayalyzed Peroxide Process for Removal of:

Thiocyanate	Total Cyanide CN_T	Method-C Cyanide	Ammonia	Metals	Ferrocyanides
NO	YES	YES	NO	YES	YES

The process did not remove thiocyanate, byproduct ammonia or residual copper all of which are potentially toxic and require additional treatment for their removal.

It was found that "the process required large quantities of expensive chemicals resulting in expected high operating costs."

The Homestake pilot plant consisted of several 0.2m³ (55 US gallon) Nalgene barrels operated in series to achieve a 2.5 hour contact period. The pilot flow rates varied from 125-200 ml/s (2.0-3.0 gpm). 100 mg H_2O_2/l, 10 mg Cu/l and 20.0 mg $FeCl_3$ were added.

The pH was maintained at 9.0 with either caustic or lime. The process was operated at ambient temperatures.

Following the oxidation sequence, the solutions were clarified and filtered under pressure through a sand filter. "Excessive chemical requirements and costs rendered the processes cost prohibitive for this application."

TRAUTMAN & OMMEN (1981) reported the same tests using 2.5 hour residence times in the reaction tanks. Altogether, 14 test programs were completed at various flow combinations. Total cyanide was reduced from 10.5 ppm to 0.5 ppm. Weak acid dissociable cyanide was reduced from 8.1 ppm to 0.2 ppm. When scale control using phosphonate was attempted, higher copper values were found in the effluent.

OK TEDI PEROXIDE DECOMPOSITION OF CYANIDE

LAMMERS (1984) mentioned the use of hydrogen peroxide for cyanide destruction in a major project milling 22,500 tpd ore with cyanide addition of about 11,250 Kg/d. The screened tailings are pumped to a tank 13 mØ x 24.5 m high agitated by a Denver draft tube agitator with 3.66 m impeller and powered by a 75 kilowatt motor.

About 1.2 Kg hydrogen peroxide solution (70%) is added per ton of ore. Sufficient copper ions are already in the solution to provide the catalyst for the reaction.

The peroxide addition is controlled automatically based on the oxidation-reduction potential of the feed to the tailings tank. This control system was developed by Degussa, the supplier of the hydrogen peroxide, and is proprietory.

KNORR & GRIFFITHS (1984) of Degussa discussed peroxide oxidation of cyanide at the Cyanide Conference held in December 1984 in Tucson, Arizona. Their process is made feasible through the use of their on-line analysis and automated process controlls described in the patent inserted below.

LAMMERS (1984b) pointed out that the Degussa peroxide addition controller was essential to achieve an affordable reagent consumption for this process.

Dear Hans,

it was very interesting meeting you in Tucson, at the conference on "Cyanide and the Environment". We hope you enjoyed the conference as much as we did, and look forward to more such stimulating meetings in the future.

We promised to send you a copy of the U.S. Patent covering the application of our cyanide detoxification process with hydrogen peroxide, and we enclose it herewith. We also take the opportunity to include some further information on Degussa and the products and processes which we offer.

Kind regards

[57] **ABSTRACT**

There is provided a continuous process for the lowering of the content of toxic materials in waste waters which also contain other oxidizable materials by quickly and continuously ascertaining the requirement of hydrogen peroxide, namely by potentiometric determination of the oxidizing agent requirement in a branched-off side-stream using a strong oxidizing agent, such as peroxymonosulfate, peroxydisulfate, permanganate, hypochlorite or ozone, which acts more quickly than hydrogen peroxide under comparable conditions.

FIG. 2

PROCESS FOR THE TREATMENT OF CONTINUOUS WASTE WATER STREAMS HAVING CHANGING CONTENTS OF DIFFERENT OXIDIZABLE MATERIALS WITH HYDROGEN PEROXIDE

BACKGROUND OF THE INVENTION

The use of hydrogen peroxide as an agent for the oxidative treatment of waste water takes on increasing significance under today's aspects of environmental protection, since hydrogen peroxide itself does not cause additional salting of the waste water but splits into water and oxygen. However, an essential condition is that the necessary amount of hydrogen peroxide can be determined automatically and controlled.

This requirement is especially true for the treatment of continuous waste water streams which contain variable amounts of different oxidizable toxic materials and only permit a relatively short time for treatment. In such cases the success of waste water treatment with hydrogen peroxide depends highly on how quickly and reliably the total requirements of oxidizing agent can be determined in the incoming waste water stream in the treatment plant. As total oxidizing agent demand (requirement) we understand that amount of active oxygen or H_2O_2 which is needed in order to be able to convert the oxidizable material in the waste water under the chosen reaction conditions into the appropriate oxidation products in each case.

Little information can be found in the technical literature as to how the total oxidizing agent requirement of a waste water can be determined automatically. The reason for this is that most of the materials occurring in waste water only contribute in small and very variable manner to the formation of a definite redox potential, that e.g. can be measured with a platinum/reference electrode pair. Therefore the oxidative waste water treatment process is operated in such a way that, while following the redox potential of the waste water, oxidizing agent is added successively until due to the presence of an excess a constant end point is established. However, in most cases this process is usable only for a batchwise treatment of waste water, since the oxidation of the various materials with H_2O_2 requires variable reaction times and therefore a constant end potential is not established immediately, even in the presence of excess H_2O_2, but only when the oxidation reactions are completed.

Thus, e.g., there is described in German Pat. No. 2,352,856 and related Fischer U.S. Pat. No. 3,970,554 a process for the detoxification of cyanide-containing waste water with H_2O_2 that permits the monitoring and control of the detoxification process and the addition of the H_2O_2 by measuring the redox potential with a silver electrode and any desired reference electrode, preferably a thalamide electrode. (The entire disclosure of the Fischer U.S. patent is hereby incorporated by reference and relied upon). However, this process is only employable in most cases for a batchwise treatment of waste water since the measurement of the redox potential shows the free cyanide content in the waste water, but permits no conclusions regarding the total oxidizing agent requirement if, besides free cyanides, other consumers of hydrogen peroxide are also contained in the waste water.

The single addition of an amount of oxidizing agent corresponding to the indication of free cyanide content

at the beginning of the waste water treatment would accordingly lead to insufficient detoxification results, because the other consumers of H_2O_2 use up a portion of the hydrogen peroxide which is needed for the cyanide oxidation. Only through multiple subsequent dosing of oxidizing agent at fixed time intervals can in these cases bring about both the desired breakdown of cyanide as well as of other oxidizable materials present. Such a stepwise approach to the goal of the process, as necessary because of the reaction time needed for the oxidation of the cyanide, does not usually permit the continuous treatment of large waste water streams because the treatment plant must be constructed so large in order to guarantee sufficient treatment time.

In Belgian Pat. No. 883,046 there is given a process for the measurement of the concentration of a specific dissolved component with redox- or ion-sensitive electrodes for the purpose of monitoring or regulating chemical processes, among others in the treatment of waste water. This process is characterized by the determination of the maximum attainable potential value by addition of excess reagent to a side stream of the system and evaluating the deviation of the starting potential as a measure of the reactive material content. For example, in this way the free cyanide content can be ascertained quickly and reliably in a continuous waste water stream and the amount of hydrogen peroxide shown to be required for the oxidation can be added. However, the process described according to Belgian Pat. No. 883,046 fails to work if there are present in waste water different oxidizable toxic materials in varying concentrations together which contribute different amounts to the formation of the redox potential. Thus, e.g., in the measurement of the cyanide potential with a silver electrode and a thalamide reference electrode under the conditions of the process described in German Pat. No. 2,352,856 (and related Fischer U.S. patent) approximately the same redox potential of about 350 mV is produced by 1 mg S^{2-}/l as by 50 mg Cn/l. Other oxidizable materials, such as sulfite, on the other hand are practically not detected at all by this redox system.

Therefore the invention is based on the problem of developing automatic system which makes possible quick and reliable determination of the oxidizing agent requirement which is needed for decreasing the toxic material concentration of a waste water under a desired limit in a continuous oxidative treatment of the waste water under fixed pH and temperature conditions.

SUMMARY OF THE INVENTION

It has now been found that this problem of the treatment of continuous waste water streams with varying contents of different oxidizable materials, especially cyanides, sulfides, sulfites, thiosulfates, thiocyanates and/or organic materials, with hydrogen peroxide for the purpose of the detoxification and reduction of the chemical and biological oxygen demand can be solved if the dosing of the H_2O_2 to the continuous waste water stream (main stream) is controlled by ascertaining the oxidizing agent demand in a small, continuously branched-off side-stream (measuring stream) parallel thereto by:

(a) adjusting the pH of the waste water in the side-stream by dosing of alkali or acid to a definite value between pH 3 and 12;

(b) continuously measuring the redox potential in the side-stream in the known manner with a platinum, sil-

ver, gold, or ion-selective electrode and any suitable reference electrode and dosing an aqueous solution of a strong oxidizing agent acting more quickly than H_2O_2 under comparable conditions, such oxidizing agent preferably being a peroxymonosulfate, peroxydisulfate, hypochlorite, permanganate or ozone, until the desired redox value is reached corresponding to the sought breakdown of the toxic material, and then always, when the strong oxidizing agent is dosed into the side-stream (measuring stream) simultaneously adding proportional amounts of H_2O_2 and other chemicals if necessary, e.g., for pH regulation, into the main-stream.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a schematic flow diagram of one form of the process of the present invention; and

FIG. 2 is a schematic flow diagram of the decyanization of blast-furnace gas wash-water by the process of the invention.

DETAILED DESCRIPTION

Referring to FIG. 1, a constant amount of waste water per unit time is continuously branched off from the waste water stream 1 (main stream) and is led as so-called measuring stream 2 separately through two measuring cells M_1 (also identified as 16) and M_2 (also identified as 18), fitted with stirring or mixing devices 10 and 12. In the measuring cell M_2, the pH and redox values of the waste water are continuously measured with pH and redox measuring devices. In measuring cell M_1 the dosing of acid or alkali takes place, which continuously establishes the pH required for measuring the redox potential. Besides this, the strong oxidizing agent is added to the measuring stream, if the measured redox potential in cell M_2 deviates from the desired redox value (set point).

Synchronous with the dosing of the strong oxidizing agent into the measuring stream 2 there is dosed into the waste water stream 1 (main stream) a proportional amount of H_2O_2. Additionally, the chemicals needed to regulate the pH in the main stream are added as soon as the strong oxidizing agent is dosed into the measuring stream 2 and H_2O_2 is dosed into waste water stream 1 (main stream).

For the exact and quick determination of the H_2O_2 requirement which is needed for decreasing the toxic material concentration to the desired limit there must be chosen a strong oxidizing agent which on the one hand reacts practically instantaneously with the toxic materials in the waste water and on the other hand has a comparable oxidation power, to that which is reached by dosing H_2O_2 into the waste water stream 1 (main stream) within the available treatment time. As indicated above, under these conditions, the most suitable strong oxidizing agents are the soluble salts of peroxymonosulfuric acid, e.g. sodium monoperoxysulfate and potassium monoperoxysulfate (caroate). However, there can also be used other strong oxidizing agents such as salts of peroxydisulfuric acid, e.g. sodium peroxydisulfate and potassium peroxydisulfate, permanganates, e.g. sodium permanganate and potassium permanganate, ozone and hypochlorites of the alkali metals and alkaline earth metals.

The addition of the H_2O_2 as well as the chemicals for pH regulation in the waste water stream 1 (main stream) is undertaken in a mixing vessel M_H (also identified as 20) containing stirring device 22 from which mixing vessel the waste water stream 1 is led into one or more reaction basins 7, 17, 27, and 37 connected in series, in which the oxidation of the various materials present can be carried out simultaneously. In the course of passing these reaction basins, can also, if necessary, a correction of the pH or subsequent dosing of oxidizing agent be carried out.

If insoluble compounds are formed in the oxidative treatment, the waste water stream must subsequently be led to devices for the separation of the sediment (not shown) before the waste water can be led into the sewer. It is also necessary to adjust the pH to the permissible range if it deviates therefrom.

The measuring stream, after passing through the measuring cells M_1 and M_2, also rejoins the waste water stream 1 (main stream) and the combined treated stream leaves through line 24.

In FIG. 1 the measuring devices are designated by the letters A, B, and C. The lines for dosing of acids, alkali, H_2O_2 and caroate into the measuring stream 2 or waste water stream 1 (main stream) are denoted by 3, 4, 5, and 6.

The process of the invention has proved successful above all in the decyanization of blast-furnace gas wash-waters. Such waste waters arise in blast furnace processes in amounts of several hundreds to over one thousand m^3/h. They contain besides considerable amounts of flue dust varying amounts of alkali cyanides, heavy metal cyanides, sulfides, sulfites, thiocyanates and other sulfur compounds as well as phenols and other organic compounds. The content of easily-liberated cyanide in these waste waters normally lies in the range of 0–10 mg CN^-/l; in disturbances of the blast furnace process or in starting up or shutting down the blast furnace the cyanide content, however, can also increase to a substantially higher value (over 100 mg CN^-/l).

For the decyanization of such waste water there has been up to now no suitable process available. The known process of chlorination has disadvantages such as the formation of toxic chlorination products, operation at very high pH values and because of this the formation of additional amounts of neutral salts in the necessary neutralization of the waste water after the detoxification before entering the sewer, which increases the amount of neutral salts arising from the chlorination reagents as well as the known dangers due to the presence of excess chlorine or hypochlorite, entirely apart from the difficulties in automatic monitoring and control of operations with these materials.

In contrast, hydrogen peroxide does not form toxic products or cause additional salting. The presence of an excess is not injurious since hydrogen peroxide decomposes to water and oxygen. The cyanide oxidation with hydrogen peroxide can also be carried out at lower pH values, preferably at pH 10; therefore less chemicals are needed for the alkalization and neutralization of the waste water and therefore less neutral salt is produced. Simultaneously, hydrogen peroxide oxidizes sulfur compounds in a lower stage of oxidation to elemental sulfur or sulfates and thiocyanates are converted into cyanates. In the presence of metallic iron or copper or iron-III ions phenols are also oxidatively broken down by H_2O_2 forming mainly dicarboxylic acids. The oxidation of organic compounds takes place partly up to CO_2 so that a significant reduction in Chemical Oxygen Demand (COD) is effected by H_2O_2 without additional increase in salt content. Aldehydes are also oxidized by H_2O_2.

Preliminary experiments have shown that for reduction of the cyanide content in blast-furnace gas washwater a significantly higher amount of H_2O_2 relative to the amount of cyanide is needed because other oxidizable materials sometimes react with the hydrogen peroxide more quickly than cyanide. Such a waste water treatment with H_2O_2 can therefore only be carried out if the addition of H_2O_2 can be controlled automatically and adjusted according to the total oxidizing agent requirement. This was made possible for the first time through use of the present invention as described in Example 2.

A further field of use for the process of the invention is e.g. the treatment of waste waters from the reproduction section of graphic plants and from film copying works whose content of toxic material in the individual waste water streams as well as in the form of waste water mixtures can be reduced to the desired limit. Besides inorganic sulfur compounds in lower oxidation stages, such waste waters always contain varying amounts of organic compounds which because of their high oxygen demand (COD, BOD) are a great stress for the biological sewage treatment plants. With the help of hydrogen peroxide, it is possible to treat such waste water from fixing, developing and clearing baths and other processes so that the biological load is substantially lower. Thus, by means of the treatment with H_2O_2 reducing substances such as thiosulfates and sulfites which are present in fixing, developing, and clearing baths can be finally oxidized up to sulfates. Simultaneously in the oxidation treatment with H_2O_2 the dissolved silver is precipitated as an insoluble mixture of Ag_2O, AgBr and Ag_2S. The recovery of silver from the sludge thus contributes to the cost of the waste water treatment.

In concentrated waste waters from such photo processes the changes in pH or redox potential occurring during the treatment with H_2O_2 can frequently be used for control of the oxidative waste water treatment, especially as these treatments can be carried out for the most part batchwise. However, such a waste water treatment is substantially more difficult if a dilute waste water with relatively low concentrations of oxidable materials is used and which, because of the large amounts of waste water, cannot be treated batchwise but must be treated continuously.

In this case the invention is based on the problem of finding a monitoring and regulating concept with whose help it is possible, by dosing H_2O_2 into a continuous waste water stream, to lower the iodine value, used here as a measure for the content of oxidizable material, from e.g. above 10 mg iodine/l to 10 mg iodine/l or lower.

To carry out the process of the invention the pH is selected in such a way that the oxidizing agents added to the measuring and waste water main streams can act optimally. This pH value or pH range can be different in the waste water main stream from that in the measuring stream.

Thus, it has been shown that in the oxidation of cyanide-containing waste water the pH in the main stream and in the measuring stream can be in the range of 6 to 12, preferably at about 9-12, the value of about 10 has proved to be especially favorable.

As redox measuring electrodes, platinum, gold, or silver electrodes or an ion sensitive electrode may be used at will and connected with any reference electrodes, e.g. a thalamide electrode.

In employing hydrogen peroxide it may also be of advantage to use activators, e.g. the substances described in German Pat. No. 2,352,856 and Fischer U.S. Pat. No. 3,970,554.

The hydrogen peroxide is employed in the normal commercial concentrations, e.g. in solutions containing 30-70 weight % H_2O_2. Higher or lower concentrations are possible, but not usual.

The materials used as strong oxidizing agent such as peroxymonosulfates, peroxydisulfates, potassium permanganate, hypochlorites or ozone are employed in concentrations which are adjusted to the oxidizing agent requirement in each case. In using potassium caroate a concentration of 45 grams $KHSO_5$/l has proven suitable.

Per mole of peroxymonosulfate there are employed 1-10 moles of H_2O_2, whereby the ratio of liters of measuring stream to liters of main stream must of course be considered.

For the decyanization of waste waters with H_2O_2 in a given case there can also be added a small amount of formaldehyde as an aid, with which the cyanide is partially converted into glycolic acid. The formaldehyde is employed in the form of commercial aqueous solutions which preferably contain 30-40 weight % H_2CO. According to the process of the invention additions of 0.1-1 mole of H_2CO/mol of peroxymonosulfate are advantageous, in which case again the ratio of liters of measuring stream to liters of main stream must be considered.

The advance in the art of the process of the invention consists essentially of the possibility of ascertaining the requirement of H_2O_2 needed for lowering the concentrations of various toxic materials in continuous waste water streams quickly and continuously as well as being able to undertake simultaneously the dosing of the hydrogen peroxide as well as the chemical aids, e.g. for regulation of the required pH in the waste water, so that it is guaranteed that, even at changing concentrations of toxic materials in the waste water, there will always take place the desired breakdown to the required limit of concentration. The process of the invention also has the advantage that the pH regulation in the waste water main stream is only then undertaken if a treatment with hydrogen peroxide is necessary. In this way reagents are saved, as well as unnecessary salting of the waste water.

Unless otherwise indicated all parts and percentages are by weight.

The process of the invention can comprise, consist essentially of, or consist of the stated steps with the stated materials.

The invention is explained more closely in the following examples.

EXAMPLE 1

There should be automatically added to a continuous waste water stream from a film copying plant an amount of H_2O_2 corresponding to the varying content of oxidizable materials with substantial avoidance of over and under dosaging. The iodine value serving here as the measure for the content of oxidizable materials should be regulated to a maximum of 10 mg of iodine per liter.

It was established in preliminary tests that the changes of the redox potential at the relatively low concentrations of oxidizable materials (iodine value 100-200 mg per liter) present in the untreated waste

water by addition of the H_2O_2 were only small and could not be utilized for automatic regulation. The pH of 6–7 present in these water samples did not change substantially during the addition of H_2O_2.

However, it was established that, even in these waste waters, significant pH-dependent changes of the redox potential (about 300–400 mV) occur if there is added to the waste water in place of H_2O_2, the solution for example of an alkali metal salt of peroxymonosulfuric acid (Caro's acid) such as potassium caroate, $KHSO_5$ (or sodium caroate). This change of the redox potential in the addition of caroate can be used as quantitative control for the treatment of waste water with H_2O_2 if the caroate addition is carried out at constant pH and the pH change caused by the addition of the acid-reacting caroate solution is compensated for by addition of caustic soda (aqueous sodium hydroxide). A platinum/calomel-electrode pair is suitable in this case for the potential measurement.

For the principle of the process of the invention see FIG. 1.

For the present example there were branched off from the waste water stream of a film copying plant (about 40 cubic meters per hour) a measuring stream (50 liters per hour) and a main stream with 2300 liters per hour. The measuring stream was led through two series-connected stirrer cells (M_1 and M_2). There was dosed into the stirrer cell M_1 the caroate solution (150 grams of caroate per liter=6.32 grams of active oxygen per liter) and in the stirrer cell M_2 there was dosed 1 N aqueous sodium hydroxide (40 grams of NaOH per liter). The stirrer cell M_2 also contains a combined pH-measuring electrode (one-line) and a platinum/calomel redox electrode pair.

With the help of a measuring and controlling apparatus the dosing of the aqueous sodium hydroxide and caroate solution into the measuring stream was controlled in such a manner that, at a constant pH of 8, there was maintained a redox potential of +150 mV. (Under these conditions with potassium iodide-starch paper there was always established a small caroate excess in the measuring stream).

Synchronous with the dosing of caroate into the measuring stream there was added to the main stream a proportional amount of H_2O_2 (50 weight % with 281 grams of active oxygen per liter). The waste water treated with H_2O_2 flowed through the reactor M_H which consisted of two series-connected reactors, each having a volume of about 750 liters of which the first reactor was equipped with a stirrer. The theoretical residence time amounted to about 20 minutes per reactor.

By determination of the iodine value of the waste water in the main stream treated with H_2O_2, the H_2O_2 dosage was adjusted so that the iodine value, which in the untreated waste water on the average amounted to 200 mg I_2 per liter, was reduced to 10 mg of iodine per liter.

The consumption of chemicals needed to reach this iodine value amounted on the average to:

(a) 400 ml of 1 N-NaOH per hour and 680 ml of caroate solution (150 grams per liter) per hour for the measuring stream (50 liters per hour) and

(b) 940 ml of H_2O_2, 50 weight %, per hour for the main stream (2.3 cubic meter per hour).

EXAMPLE 2

At the blast furnace of a metallurgical plant for the production of pig iron there arise per hour about 1,400–1,800 cubic meters of blast-furnace gas wash-water which contains, besides iron oxide and zinc oxide ore and slag particles, calcium compounds etc, varying amounts of dissolved oxidizable materials such as sulfites, sulfides, phenols and also alkali cyanides in the order of magnitude of 0–10 mg CN^- per liter. For example, the total analysis of such a waste water showed the following contents:

2.15 mg CN^-/l total cyanide according to DIN 38 405-D 13.1

1.95 mg CN^-/l direct argentometrically determinable cyanide

16 ml sediments per liter waste water

0.5 mg Cu/l total

0.3 mg Ni/l total

17 mg Zn/l total

168 mg Fe/l total

0.3 mg Cu/l dissolved in the filtrate

0.2 mg Ni/l dissolved in the filtrate

<0.05 mg Zn/l dissolved in the filtrate

<0.3 mg Fe/l dissolved in the filtrate

The pH of the waste was about 6. The permanganate consumption was 1049 mg $KMnO_4$ per liter of waste water corresponding to 265.6 mg active oxygen per liter or 1,130 mg H_2O_2 (50 weight percent) per liter or 5,600 mg potassium caroate (45 percent $KHSO_5$) per liter of waste water.

During the temporary shutting-down of the blast furnace for the purpose of repair there was established in the blast-furnace gas wash-water the following maximum content of unwanted substances:

197 mg CN^-/l direct argentometrically determinable cyanide

142 mg CN^-/l easily-liberated cyanide according to DIN 38 405-D 13.2

820 mg Fe/l total

7.6 mg Pb/l

87.2 mg Zn/l

39 mg S^{--}/l

DIN stands for German Industrial Standard.

Up to now, the waste water of this blast furnace was merely continuously clarified in a sedimentation plant (Bischoff-basin) and, mixed with other process waters, led into a river; only during the starting-up and shutting-down of the blast furnace, i.e. at higher cyanide contents in the blast-furnace gas wash-water, there was carried out a treatment with hypochlorite bleach solution. This process, however, was not satisfactory because of the above-mentioned side effects.

In the course of investigating all possible processes for the decyanization of this waste water there could also be tested the treatment with hydrogen peroxide using the measuring and control techniques of the invention. Thereby it was found that the content of easily liberated cyanide, (using the residence time in the sedimentation basin, can be quickly and safely reduced to values below 0.1 mg CN^- per liter (according to DIN 38405-D. 13.2) if the ascertained amount of H_2O_2 in the waste water determined by redox controlled addition of potassium caroate in a side-stream (measuring stream) is added to the collecting tank installed before the sedimentation plant and simultaneously there is added a less than stoichiometric amount of formaldehyde relative to the amount of H_2O_2. In this way, above all at low cya-

nide concentrations, there is caused a partial conversion into glyconitrile which, under the action of H_2O_2, very quickly hydrolyzes to glycolic acid and in the presence of calcium ions substantially precipitates as insoluble calcium glycolate.

The principle of the measuring and control technique which is employed for the decyanization of the blast-furnace gas wash-water with H_2O_2 and H_2CO is represented in FIG. 2.

For the control of the addition of chemicals there is branched off from the blast-furnace gas wash-water stream a side-stream of about 2 cubic meters of waste water per hour and led back again as a loop stream into the collecting tank. From this loop stream there is continuously drawn off exactly 100 liters of waste water per hour and led as a measuring stream through two mixing cells M_1 and M_2. In the mixing cell M_1 the pH of the waste water is continuously measured with a glass electrode and regulated by automatically dosing 10% aqueous sodium hydroxide to pH 10±0.5. In the mixing cell M_2 the redox potential of the waste water is continuously measured with a silver and a thalamide reference electrode and regulated by automatically dosing a 10% caroate solution containing 4.5% $KHSO_5$ to at least +650 mV. This potential corresponds to the desired degree of detoxification. In order to be able to measure this potential there is continuously dosed into the measuring stream 2 at least 0.001 mg Ag NO_3 and 2.5 mg KI per liter. The output of the metering pump for the caroate solution was regulated so that in normal operation of the blast furnace the toxic material content could be reduced from maximally 10 mg CN^- per liter in the presence of other oxidizable materials practically instantaneously to a residual content of <0.1 mg CN^- per liter through the added amount of caroate solution, (e.g. dosing output 1 liter of 10% caroate solution per hour). The pump for dosing of caroate solution into the measuring stream is controlled via the set point of the redox measuring device. When the potential falls below the set point (=specified mV value) the pump is switched on, on exceeding the same set point it is switched off again.

Parallel to the dosing of the caroate solution if the potential falls below the set point of the redox measuring amplifier the addition of chemicals into the main stream is also controlled. The pH of the waste water main stream, which already is partly alkalized by lime, is regulated by dosing aqueous sodium hydroxide into the collecting tank to pH 10±0.5 with the aid of a pH measuring device in the loop stream line, and proportional amounts of 37% formaldehyde solution and 50 weight percent hydrogen peroxide are also dosed to the collecting tank. The dosing output of the chemical pumps was thereby chosen, so that in the normal operation of the blast furnace and a waste water amount of 1,500 cubic meters per hour there could be dosed per liter of caroate solution (in the measuring stream) 620 liters of H_2O_2 (50 weight percent) and 170 liters of H_2CO (37 weight percent) as well as about 3000 liters of NaOH (20 weight percent) in the main stream.

The effective consumption of chemicals in the normal operation of the blast furnace is about 250 liters of H_2O_2 (50 weight percent) per hour and 70 liters of H_2CO (37 weight percent) per hour; additionally there is needed on the average 840 liters of NaOH (20 weight percent) per hour for the final alkalization. A re-neutralization of the waste water after the oxidative treatment was not necessary; the pH of the treated waste water after the separation of sediment is always below 9.

An analytical investigation of the degree of detoxification according to DIN 38 405-D 13.2 carried out at regular intervals showed that under these conditions the content of easily-liberated cyanide in the waste water could always be reduced to a value below 0.1 mg CN^-/l. The treatment thus fully met the requirements.

If the content of oxidizable material in the waste water increases, both the output of the caroate pump and proportionally that of the chemical pumps for the main stream must be increased. The signal for this is given when, during permanent operation of the chemical dosing pumps, the specified redox potential is no longer exceeded.

In the treatment of blast-furnace gas wash-water it is also necessary to ensure the correct functioning of the measuring electrode by cleaning at regular intervals (about 1 hour), since some materials in the waste water (above all the alkaline earth metal compounds and the CO_2) lead in the alkaline pH range to scale formation. Such a cleaning of the electrodes can be effected very easily by dosing into the mixing cell M_1 of the measuring stream at regular intervals a small amount of medium strength hydrochloric acid or nitric acid. This dosing is controlled automatically by a time switch.

The entire disclosure of German priority application P 3125452.7 is hereby incorporated by reference.

EXAMPLE 3

In the synthesis of an intermediate for the production of herbicides there arise 1000 l/h of waste water which, in addition to neutral salts and sulfur compounds, also contain other organic reaction products. As a result there is a high COD value of about 17,000 mg O_2/l. The pH of the waste water is 7.

Difficulties occurred in treating this waste water in a biological purification plant because of the high COD value. The lowering of the COD value by a complete oxidative treatment with chemicals was excluded for reasons of cost. Therefore the possibility was investigated of changing the materials contained in the waste water by a chemical treatment in such a way that they could be completely broken down in a subsequent biological purification plant.

It was established in preliminary tests that in the treatment of the waste water with H_2O_2 in the acid pH range there occurred an intermediate precipitation of certain substances, which in the further oxidation either partially or completely redissolved. However, if the reaction was carried out with less than stoichiometric amount of H_2O_2 based on the initial COD of the waste water and the intermediately formed precipitate was separated off, then a substantially greater reduction of the COD was produced than would be expected from the oxidation agents alone. However, this oxidation reaction could not be followed and controlled up to now. Therefore the practical use of these oxidation reactions was linked to high analytical expense. By using the principle of the invention described herein for controlling waste water treatment processes with H_2O_2, in this case also a simple and economical solution of the waste water problem was found.

To ascertain the maximum amount of oxidizing agent required, there was continuously branched off from the waste water stream of 1,000 l/h a side-stream of 1 l/h and fed into a diluting water stream of 100 l/h. This diluted waste water side stream was then adjusted to a

pH of 12 by dosing aqueous sodium hydroxide solution and there was continuously dosed a caroate solution (45 grams $KHSO_5$/l) until the redox potential measured with a Pt-thalamide electrode pair increased from +700 mV to +800 mV.

Parallel to the diluted waste water side stream, the waste water main stream (1000 l/h) was first adjusted to a pH of 3 by dosing sulfuric acid, and then 50% H_2O_2 was always dosed when caroate solution was dosed into the diluted waste water side stream. The ratio of caroate dosed into the diluted waste water to H_2O_2 dosed into the waste water main stream was hereby so regulated that in dosing 1 liter of caroate solution into the diluted waste water side stream, there were introduced 16 liters of 50 weight % H_2O_2 into the main waste water stream. This amount of H_2O_2 corresponds to about 55% of the oxidizing agent requirement for the total oxidation based on the initial CGD of the waste water of 17,000 mg O_2/l.

After a reaction time of 1.5 hours and separation of the precipitates formed in the course of this treatment, the filtrate of the waste water main stream had a COD value of only 3,570 mg O_2/l; this corresponds to a reduction in COD of 79% based on the original COD, or 144% based on the amount of oxidizing agent used.

It was also determined, that the waste water after this treatment could be completely treated in a biological sewage plant without difficulty.

EXAMPLE 4

A continuous waste water stream from a hardening shop which contains varying amounts of nitrite (15 to 120 mg $NO^-{}_2$/l) should be treated by automatically controlled addition of H_2O_2 so that, on the one hand there is guaranteed a complete oxidation of the nitrite to nitrate, and on the other hand that H_2O_2 is not dosed in excess.

In preliminary tests on a laboratory scale it was established that in the oxidation of this waste water with H_2O_2 in the acid pH range there occurred only a very small change of the redox potential measured with a gold-thalamide electrode pair. This small change could not be used for control.

However, it was also established that in the oxidative treatment of this hardening-shop waste water there always occurred a clear jump in potential (from 320 to 640 mV) if, instead of H_2O_2, sodium hypochlorite was used as the oxidizing agent. This change of redox potential can be used as a standard for the treatment of waste water with H_2O_2 if the NaOCl addition takes place at a pH below 3 and the change in pH caused by the addition of alkaline NaOCl solution is compensated for by the addition of acid. For the measurement of the potential gold or platinum electrodes are suitable in conjunction with the customary reference electrodes employed in the practice.

CARRYING OUT OF THE OXIDATIVE TREATMENT

There was branched off from the waste water stream of a hardening shop (6 m^3/h) for the present example a measuring stream of 100 liters per hour which was led through two measuring cells connected in series. There were fed into the stirrer cell 1 sulfuric acid (accumulator acid) and sodium hypochlorite solution (25 grams NaOCl/l). The stirrer cell 2 contained a combined pH measuring electrode and a gold/thalamide electrode pair.

By using a suitable measuring and control apparatus of customary construction the dosing of acid and NaOCl into the measuring stream was controlled so that at a pH of 3 or below there was maintained a redox potential of above +1600 mV. (Under these conditions with potassium iodide-starch paper there was always established only a slight excess of NaOCl in the measuring stream.)

Parallel to the dosing of NaOCl into the measuring stream, the pH in the main stream was first regulated to 3.5 or below and then there was always dosed a proportional amount of H_2O_2, 50 weight %, when NaOCl was dosed into the measuring stream. The thus treated waste water was then led into a further reaction basin (1.5 m^3) and from there into final stirrer container (1.5 m^3) in which the neutralization with milk of lime was carried out. Then the sediment ($CaSO_4$) contained in the waste water (mainstream and measuring stream) was separated off by means of an inclined clarifier and substantially dewatered in a filter press. In this manner there was always observed in the discharges from the starting clarifier and the filter press a nitrite content below 1 mg $NO^-{}_2$/l; the excess content of H_2O_2 was likewise only less than 5 mg H_2O_2/l.

In order to obtain these discharge values there were only needed on the average the following amounts of oxidizing agents

(a) 420 ml of hypochlorite solution per hour containing 25 grams NaOCl/l for the measuring stream (100 l/hour).

(b) 520 ml H_2O_2, 50 weight %, per hour for the mainstream (6 cbm/hour).

What is claimed is:

1. A process for the treatment of a continuous main waste water stream having a varying content of different oxidizable materials with hydrogen peroxide for the purpose of detoxification and reduction of the chemical oxygen demand and biological oxygen demand, comprising diverting a small portion of the main waste water stream to form a side stream and controlling the amount of hydrogen peroxide added to the main stream by ascertaining the oxidizing agent demand in the side stream by:

(a) adjusting the pH of the waste water by dosing of alkali or acid continuously to a constant pH value between 3 and 12,

(b) continuously measuring the redox potential with a platinum, silver, gold, or ion selective electrode and a reference electrode and dosing an aqueous solution of a strong oxidizing agent acting more quickly than H_2O_2 under comparable conditions until the desired redox value is reached corresponding to the sought breakdown of the toxic material, and then always when the strong oxidizing agent is dosed into the side stream simultaneously adding into the main stream proportional amounts of H_2O_2 and any necessary further chemicals.

2. A process according to claim 1 wherein the materials to be removed are selected from the group consisting of cyanides, sulfides, sulfites, thiosulfates, thiocyanates, and/or organic oxidizable material.

3. A process according to claim 2 wherein the material to be removed includes cyanide.

4. A process according to claim 3 wherein there is added to the main stream a chemical reagent which regulates the pH.

5. A process according to claim 3 wherein the strong oxidizing agent is a peroxymonosulfate, peroxydisulfate, permanganate, hypochlorite or ozone.

6. A process according to claim 5 wherein the strong oxidizing agent is a salt of peroxymonosulfuric acid.

7. A process according to claim 6 wherein the salt is potassium caroate.

8. A process according to claim 6 comprising lowering the cyanide content in the waste water by

(a) continuously controlling the pH of the side stream to 10±0.5 by adding alkali or acid thereto;

(b) continuously following the cyanide content in the side stream by measuring the cyanide-specific redox potential with a silver-thalamide electrode pair and dosing an aqueous solution of peroxymonosulfate until there is indicated a redox potential of at least +650 mV; and

(c) adding to the main stream an amount of hydrogen peroxide potential to the amount of peroxymonosulfate used in the side stream and controlling the pH during the addition to a value between 9 and 12.

9. A process according to claim 8 wherein the pH is controlled in the main stream to 10±0.5.

10. A process according to claim 9 wherein per mole of peroxymonosulfate used in the side stream there is fed into the main stream 1-10 moles of H_2O_2 times the ratio of liters in the main stream to the liters in the side stream.

11. A process according to claim 10 wherein there is fed into the main stream 0.1-1 mole of formaldehyde per 1-10 moles of H_2O_2.

12. A process according to claim 8 wherein per mole of peroxymonosulfate used in the side stream there is fed into the main stream 1-10 moles of H_2O_2 times the ratio of liters in the main stream to the liters in the side stream.

13. A process according to claim 12 wherein there is fed into the main stream 0.1-1 mole of formaldehyde per 1-10 moles of H_2O_2.

14. A process according to claim 2 wherein there is added to the main stream a chemical reagent which regulates the pH.

15. A process according to claim 2 wherein the strong oxidizing agent is a peroxymonosulfate, peroxydisulfate, permanganate, hypochlorite or ozone.

16. A process according to claim 15 wherein the strong oxidizing agent is a salt of peroxymonosulfuric acid.

17. A process according to claim 16 wherein the salt is potassium caroate.

18. A process according to claim 15 wherein there is employed as the strong oxidizing agent a peroxymonosulfate and per mole of peroxymonosulfate used in the side stream there is fed into the main stream 1-10 moles of H_2O_2 times the ratio of liters in the main stream to the liters in the side stream.

19. A process according to claim 15 wherein the waste water contains a sulfur compound which is a sulfide, sulfite, or thiosulfate and the content of the sulfur compound can be expressed by the iodine value which is the iodine consumption of the waste water in mg I/l and the process comprising reducing the iodine value by

(a) continuously controlling the pH of the side stream to a constant pH in the range of 3 to 12 by adding acid or alkali;

(b) continuously feeding into the side stream an aqueous solution of peroxymonosulfate whose amount is regulated so that therewith the redox potential of the side stream is continuously maintained at a constant mV value which is characteristic for a specific predetermined reduction of the iodine value;

(c) adding to the main stream an amount of hydrogen peroxide proportional to the consumption of peroxymonosulfate in the side stream and controlling the pH to a value between 3 and 12.

20. A process according to claim 19 wherein the pH in the side stream is controlled to a value between 6 and 10 and the pH in the main stream is controlled to a value between 6 and 10.

DESTRUCTION OF CYANIDE IN GOLD AND SILVER MINE PROCESS WATER

O. B. Mathre and F. W. DeVries
E. I. du Pont de Nemours & Co.
Wilmington, DE 19898

ABSTRACT

Addition of Kastone® peroxygen compound and formaldehyde to cyanide gold extraction process effluents, containing at least 5 mg soluble copper per liter, will oxidize acid-dissociable cyanide to levels less than 0.2 mg per liter, without appreciable oxidation of thiocyanate. Most of the copper precipitates and is removed by filtration of the treated solutions. The treatment can be completed in less than 2 hours when the excess of hydrogen peroxide over the cyanide is about 75-100 mg per liter. The excess hydrogen peroxide destroys residual formaldehyde and then is catalytically decomposed by the copper-containing solids that separate, so it will not interfere with subsequent operations.

A pilot plant using this technology has been operated for more than four months at rates from 1-2 gpm. Clear, filtered effluent containing less than 0.2 mg acid-dissociable cyanide per liter has been produced.

A paper presented at the annual meeting of the Metallurgical Society of AIME, February 23, 1981, Chicago, IL.

Introduction

The extraction of gold and silver from ore with alkaline cyanide solutions has been an important process for about ninety years. The waste water from this operation generally contains variable amounts of sodium cyanide, acid-dissociable complex metal cyanides and thiocyanate. Some waste waters may also contain oxidizable sulfur species such as sulfide, polysulfide, sulfite and thiosulfate. Routes for the formation of copper cyanide, refractory iron cyanides and thiocyanates in gold and silver extraction are shown in figure 1.

Figure 1

Gold and Silver Extraction

$$FeS + xs\ CN^- + Air \xrightarrow{OH^-} Fe(CN)_6^{-4} + CNS^-$$

$$Copper\ (Carbonate\ ore) + xs\ CN^- \xrightarrow{OH^-} Cu(CN)_2^- + CNO^-$$

$$S_n^{-2} + n\,CN^- \longrightarrow n\,CNS^- + S^{-2}$$

State and Federal guidelines and regulations propose or specify limits on the concentration of cyanide, free and complexed, that may be discharged to streams and in some cases sanitary sewers. The limits set by the regulatory authorities are generally at levels that require some type of cyanide analysis methodology that is used to define the cyanide content of the stream.

Oxidation with Chlorine

Alkaline chlorination is commonly used to destroy cyanide in waste process water. It destroys free cyanide and cyanide complexed with common metals such as cadmium, chromium, copper, gold, nickel, silver and zinc. It does not destroy the cyanide present as ferrocyanide or ferricyanide. It also reacts with thiocyanates and other components of waste streams, which may not require destruction and can produce undesirable by products. The net chemical reactions are shown in figure 2.

Figure 2

Process Effluent Treatment Alkaline Chlorination

$$CNS^- + 4\,OCl^- + 2\,OH^- \longrightarrow CNO^- + SO_4^{-2} + 4\,Cl^- + H_2O$$

$$CN^- + OCl^- \longrightarrow CNO^- + Cl^-$$

$$2\,Fe(CN)_6^{-4} + OCl^- + H_2O \longrightarrow 2\,Fe(CN)_6^{-3} + 2\,OH^- + Cl^-$$

$$2\,Cu[I] + OCl^- + H_2O + 2\,OH^- \longrightarrow 2\,Cu(OH)_2 + Cl^-$$

It was known that thiocyanate, a common by-product of cyanide ore leaching, would react with hypochlorite under conditions used for alkaline chlorination of cyanide compounds. Since waste water from cyanide gold and silver extraction processes usually contains thiocyanate in substantial quantities, it is necessary to add enough alkaline hypochlorite to destroy both the compounds. These reactions proceed in steps, but we will consider the net reactions shown in the first two equations in figure 2. It is apparent that the presence of moderate amounts of thiocyanate in a waste stream will substantially increase the chlorine demand of the waste stream.

Both synthetic and real process solutions were subjected to standard alkaline chlorination conditions, except that the amount of hypochlorite added was limited to that required for cyanide destruction plus an excess that ranged from 10-100% of the calculated value. Analysis of the solutions for cyanide and thiocyanate showed that the thiocyanate reacted preferentially with the hypochlorite and that the cyanide concentration was almost unchanged. This observation confirms other data that enough hypochlorite must be added to the waste stream to destroy both the thiocyanate and the cyanide to reduce the measured levels of acid-dissociable cyanide in the treated effluent. Figures 3 and 4 show typical results.

Figure 3

Figure 4

Even if sufficient chlorine has been added to destroy the thiocyanate as well as the cyanide, there is a further problem: It has been found in analytical method evaluation that solutions containing 0.1-5 mg cyanide per liter and more than 10 mg thiocyanate per liter will show a positive test for cyanide after treatment with an excess of chlorine even for 30 minutes. The analytical samples were dechlorinated with either ascorbic acid or sodium arsenite, preserved with sodium hydroxide and analyzed for acid-dissociable cyanide and for total cyanide by the official methods. Cyanide values greater than 0.1 mg/l were obtained. This suggests that alkaline chlorination of waste waters that contain substantial quantities of thiocyanate can yield effluents that may not meet regulatory requirements for discharge unless different alkaline chlorination process conditions or sample-handling techniques are used.

Oxidation with Peroxide

It was reported by Masson in 1907 that hydrogen peroxide would react with alkaline sodium cyanide solutions.(1) The kinetics of the reaction given in the paper showed that the time required for reduction of cyanide from 50 mg/l to less than 0.5 mg/l would be more than 3 hours even when the initial molar ratio of hydrogen peroxide to cyanide was as high as five. During the period 1968-1971 it was reported that the reaction between hydrogen peroxide and cyanide was promoted by addition of compounds such as formaldehyde and soluble copper salts.(2-5) The reaction rate was increased so that it became a viable candidate for destruction of cyanide in process effluents. It also was shown that substantially improved hydrogen peroxide reaction efficiency could be obtained by addition of decomposition stabilizers. This stabilized hydrogen peroxide, known as Kastone® peroxygen compound, is used in combination with formaldehyde promoter for commercial destruction of cyanide. The net chemical reactions are given in figure 5.

Figure 5

Process Effluent Treatment - Hydrogen Peroxide

$$2Cu(CN)_2^- + 5H_2O_2 \longrightarrow 2Cu^{+2} + 4CNO^- + 5H_2O$$

$$2Cu^{+2} + 5CN^- + 2OH^- \longrightarrow 2Cu(CN)_2^- + CNO^- + H_2O$$

$$CN^- + H_2O_2 \longrightarrow CNO^- + H_2O$$

$$CN^- + HCHO + H_2O \longrightarrow HOCH_2CN + OH^-$$

$$HOCH_2CN + H_2O \xrightarrow[OH^-]{H_2O_2} HOCH_2CONH_2$$

Since Kastone® technology was developed for the plating industry, the effect of thiocyanate on the process had not been examined. We found that cyanide was selectively oxidized in alkaline solution by formaldehyde or soluble-copper promoted hydrogen peroxide in solutions containing thiocyanate. Analysis showed that generally less than 10 percent of the thiocyanate was destroyed. The cyanide found in the treated solutions was less than 0.2 mg per liter. The copper-promoted system generally gave cyanide residual values below 0.05 mg per liter. The results obtained for several typical tests are given in figure 6.

Treatment of Field Samples

Cyanide gold and silver mine process effluents frequently contain soluble copper cyanide complexes. Synthetic process solutions containing sodium cyanide, copper cyanide complex, ferrocyanide and thiocyanate were treated with Kastone® peroxygen compound at pH = 8.5-10.0 and 30°C. The addition of as little as 5-10 mg formaldehyde per liter to these solutions reduced the treatment time by as much as 40% to less than 2 hours and reduced the final level of cyanide as measured to less than 0.1 mg per liter. The thiocyanate measured at the end of the reaction was generally within 2-5% of the value of the initial sample (25-150 mg/liter). For samples containing 5-10 mg

cyanide per liter as sodium and copper cyanide, 75-125 mg hydrogen peroxide per liter was adequate for reduction of cyanide to levels below 0.1 mg/l in 2 hours.

Cyanide gold extraction process effluents containing 8-25 mg acid-dissociable cyanide, 3-10 mg soluble copper per liter and 75-250 mg thiocyanate per liter, were treated with formaldehyde and hydrogen peroxide under conditions used for the synthetic process solutions. It was shown that the acid-dissociable cyanide could be reduced to levels below 0.1 mg/liter in these solutions in less than two hours.

No destruction of thiocyanate was found by the colorimetric iron method. Based on this work it is concluded that the addition of 5 mg formaldehyde per liter and 75-100 mg hydrogen peroxide per liter to an effluent containing 4-6 mg soluble copper per liter and 5-20 mg acid-dissociable cyanide per liter is a good choice. The pH should be maintained between 9 and 10, and the temperature should preferably be between 20°C and 40°C to reduce cyanide levels to below 0.1 mg/l within 2 hours. The results obtained on mill effluents, some of which contained additional cyanide and copper (I) to cover anticipated operating ranges, are summarized in figures 7 and 8. The data are consistent with these obtained with synthetic solutions.

Addition of only 5 mg formaldehyde per liter to a natural mill effluent provided rapid destruction of acid dissociable cyanide to levels below 0.1 mg per liter in less than two hours. Figure 7 shows that cyanide destruction to levels below 0.1 mg per liter can be achieved even when the copper present in a mill effluent is much higher than required for efficient process operation.

Kinetics

It is important to provide sufficient time for the reaction to proceed as shown in figures 9 and 10. The rate of destruction of cyanide is increased towards the end of this reaction because of the increase in the ratio of hydrogen peroxide to residual cyanide. This can be explained by the kinetic rate equation derived by Masson(1):

$$\frac{d\left[(CNO^-) + (CO_3^{-2})\right]}{dt} = k\,(H_2O_2)\,\left[(CN^-) + (\text{formate})\right]$$

An excess of 40-70 mg hydrogen peroxide per liter over that required for the oxidation of solution components has been sufficient to provide an effluent containing less than 0.1 mg acid-dissociable cyanide per liter.

Figure 9

Figure 10

Treatment of both synthetic and real effluents with Kastone® peroxygen compound with or without formaldehyde yielded a precipitate that contained a mixture of basic salts that contained copper, iron, calcium, nickel and zinc salts that were quite easy to filter. Samples were analyzed for copper, iron and nickel by atomic absorption spectroscopy. Copper and nickel levels obtained were less than 0.1 mg/liter and iron levels were reduced to less than 0.3 mg/liter. The data in figure 11 shows typical data obtained in lab tests with synthetic solutions.

Pilot Plant Schematic

Pilot Plant Operation

This work has been done using a batch treatment concept. Based on experience with cyanide waste treatment installations, this chemistry can be scaled up on a batch basis or in a continuous treatment process if sufficient residence time is provided to allow the reaction to go to completion. The process is currently being evaluated in a pilot plant located at the Homestake Mining site in Lead, South Dakota. It has a 9-stage, cascaded, stirred-reactor design. A schematic of the feed, mixing and the first three reactor stages is shown in figure 12. The cascaded reaction system was designed to treat 1-2 gpm. It has operated continuously for more than 4 months treating mixed effluent from the mill and the mine. Filtered effluent has been clear. Acid-dissociable cyanide has been reduced to levels below 0.2 mg per liter but has not yet reached 0.05 mg per liter.

Since mill effluent has been treated in the laboratory to give lower levels of acid-dissociable cyanide than that obtained from the pilot plant, it is concluded that a component in the mine effluent is a contributing factor to the higher cyanide content (figure 11). Work on this problem is in progress.

Analytical

During this study a simplified process control technique was developed. A silver/sulfide ion-specific electrode was used to monitor the change in cyanide ion concentration in the solution. A change in concentration by a factor of 10 changes the electrode potential (vs. a reference electrode) by about 118mV. This electrode has been particularly useful in determining when the reaction between the cyanide and the hydrogen peroxide is rapid and when it has gone to its final level. Reflux distillation analysis generally gave higher values of measured cyanide than the free cyanide ion calculated from direct electrode measurements. We conclude that the silver/sulfide ion-specific electrode is a useful process monitoring tool, but actual cyanide concentration in treated water should be measured in samples taken from the process and analyzed by tested methodology.

Conclusion

Copper-formaldehyde promoted hydrogen peroxide selectively destroys cyanide in the presence of thiocyanate in a "clear" gold milling process effluent. Laboratory tests have given clear filtered effluents containing less than 0.05 mg acid-dissociable cyanide per liter and 0.12 mg dissolved copper per liter. Pilot plant operation with mixed gold mill and mine effluent has given filtered effluents containing 0.15 mg acid-dissociable cyanide per liter and 0.15 mg dissolved copper per liter. The clarity of the pilot-plant filtered effluent has been below 5 NTU turbidity units.

ERGO FREE CYANIDE REMOVAL WITH IRON

At ERGO (East Rand Gold and Uranium Company Ltd.), 50 m^3/hour of raffinate from the acid uranium recovery plant containing 6,400 mg/l iron due to acid leaching of concentrate at a low pH of less than 2 is added to the gold plant residue containing repulped calcine which has been leached at pH 10.5 with cyanide and filtered for pregnant gold solution recovery. The raffinate drops the pH of the calcine residue to about 7.5. The low pH and the air agitation in the pachuca destroy most of the free cyanide, and the balance is converted by the high iron concentration in the raffinate to stable iron cyanide complexes.

Raffinate-treated gold plant residue was, until recently, pumped to a separate calcine tailings dam with the decanted water as effluent being injected into the tailings dam feed pipelines. Currently, the cyanide-free calcine residue is deposited directly with the flotation tailings to the ERGO tailings dam.

ERGO CYANIDE REMOVAL BY ACTIVATED CARBON

The new CIL installation for the recovery of additional gold from flotation tailings at ERGO utilizes the last seven of eleven carbon contacting stages for cyanide removal at the time of the visit to this plant, the CIL installation had not yet been installed, and no information was available about how carbon reduces cyanide levels in a pulp. However, it is known that at near neutral or slightly acid pH, activated carbon in the presence of low base metal levels will cause cyanide degradation at a rapid rate. At the end of this chapter, reference is made to reputed methods of recovering cyanide using activated carbon. It is not known which of these approaches is used at ERGO, although it is suspected that it is the former destruction process. After treatment, these tailings advance to the new disposal dam.

The ERGO pulps contain very low gold values in the first place. It is found that the lower the cyanide tenor in a pulp, the more effectively gold adsorbs onto carbon.

Details of ERGO's cyanide destruction process will likely be published in due course; meanwhile, information could be requested from:

PRUSSIAN BLUE PRECIPITATION OF CYANIDE

A second process employing sodium sulfite has been developed and patented as a joint program between a California consulting firm, Engineering & Technical Consultants Inc. and Homestake Mining Company. It is also known as the ETC-HMC Process.

The process has been developed to treat mine effluents containing 10-200 ppm total cyanide.

The process requires five steps which have been piloted on a continuous basis at up to 5000 gallon tank capacities (residence time not specified).

The technology is owned jointly by Homestake Mining Company and Engineering & Technical Consultants Inc.:-

ENGINEERING AND TECHNICAL
CONSULTANTS, INC.
1068 Edenbowers Lane
Redwood City, CA 94061
(415) 364-5549
Dr. Roy G. Neville

DR. NEVILLE is actively marketing the process in Canada and the U.S.A.

Step 1

Adjust the pH of the solution or pulp to pH 7 or 7.5.

Step 2

Add 100-300 ppm sodium metabisulfite. The amount to be added can be determined experimentally for each solution.

The $Na_2S_2O_5$ dissolves in water to form 2 molecules of sodium bisulfite while further reducing the pH to around 5. Some buffering effects also take place.

$$Na_2S_2O_5 + H_2O = 2\ NaHSO_3$$

Step 3

This stage is operated at pH 5-5.2. Ferrous sulfate is added at 200-300 ppm, again the precise amount depends on the specific solution.

$$Fe^{II} + 6\ CN^- \text{ (free)} = [Fe(CN)_6]^{4-}$$

THE E.T.C./HOMESTAKE CYANIDE REMOVAL PROCESS

In response to numerous inquiries regarding the cyanide removal process the following information is presented.

The process was developed by Engineering & Technical Consultants and Homestake Mining Company as part of an extensive experimental study to discover a method which would effectively remove free cyanide, and the complex cyanides of various metals, from waste water produced in the extraction of gold, by treating gold-bearing ores with sodium cyanide. In addition to free cyanide (CN^-), and complex cyanides (e.g. ferrocyanide, cuprocyanide, etc.), the waste water typically contains thiocyanate (SCN^-), as well as several hundred parts per million (ppm) of other anions (e.g. sulfate, chloride, bicarbonate, etc.), and cations (e.g. sodium, calcium, magnesium, etc.). A cyanide removal process was sought which would be rapid, dependable, economically feasible, and which would reduce or completely eliminate "total" cyanide (i.e. free cyanide and complex metal cyanides), without unnecessarily reacting with non-toxic ions present in the water.

Chemistry of the Process

After a thorough experimental study of several potentially feasible chemical processes (e.g. chlorination, peroxidation, ozonation, etc,), it was discovered that treatment of cyanide-containing waste water with ferrous ion (Fe^{2+}) and sulfurous acid (H_2SO_3, from sulfur dioxide),

or bisulfite ion (HSO_3^-, from $Na_2S_2O_5$), removed total cyanide to levels that meet most environmental regulations. The following chemical equations illustrate the sequence of reactions that occur:

1. Addition of ferrous ion (e.g. Fe^{2+} as $FeSO_4$) converts the free cyanide (CN^-) to ferrocyanide ion ($[Fe(CN)_6]^{4-}$):

$$Fe^{2+} + 6\ CN^- = [Fe(CN)_6]^{4-} \qquad (1)$$

2. Excess ferrous ion reacts immediately with ferrocyanide ion to produce Prussian blue (ferric ferrocyanide, $Fe_4[Fe(CN)_6]_3$), by reaction with dissolved atmospheric oxygen in the water:

$$2\ FeSO_4 + 2\ Fe(HSO_4)_2 + 3\ Na_4[Fe(CN)_6] + O_2 = Fe_4[Fe(CN)_6]_3 + 6\ Na_2SO_4 + 2\ H_2O \qquad (2)$$

3. A very small amount of free cyanide (ca. 0.1-0.2 ppm) remains in equilibrium with ferrocyanide ion after ferrous treatment. This minute concentration of free cyanide ion is reduced by the sulfurous acid (or bisulfite ion) present to non-toxic ammonium formate, which rapidly decomposes in the environment to ammonia, carbon dioxide and water. Catalyzed by the ferrous ion, sulfurous acid (or bisulfite ion) adds across the triple bond of the cyanide ion; to form a transitional, unstable intermediate aminomethanedisulfonate ion, which immediately decomposes to ammonium formate:

$$4\ H_2O + 2\ SO_2 + CN^- = H.COONH_4 + H_2SO_3 + HSO_3^- \qquad (3)$$

Reactions 1, 2, and 3 occur simultaneously in the mildly acidic (ca. pH 4-5) solution. In dilute aqueous cyanide solutions, the amount of Prussian blue formed is very small. Consequently, although it is extremely insoluble, it does not quantitatively precipitate.

However, merely by raising the pH of the solution to 8.0-9.0, the excess ferrous ion is immediately precipitated as ferrous hydroxide, which encapsulates the Prussian blue particles and quantitatively precipitates them.

The mild alkalinity of the solution has the additional advantage that the very minute amount (usually less than 0.1 ppm) of ammonium formate (produced by catalytic reduction of CN^- by H_2SO_3 or HSO_3^-) is decomposed to environmentally acceptable levels of ammonia, which is rapidly lost to the atmosphere:

$$H.COONH_4 + OH^- = H.COO^- + H_2O + NH_3 \qquad (4)$$

By means of these very fast, simultaneous reactions, both the free and complex metal cyanides are removed from solution. The resulting clear, colorless solution, on analysis, is found to contain total cyanide that is either undetectable, or virtually undetectable, by the so-called "standard reflux method", as recommended by the United States Environmental Protection Agency, and as described in the textbook, Standard Methods for the Analysis of Waste Water. Depending on the concentration of cyanide in the waste water, different concentrations and ratios of ferrous and bisulfite ions are used. For efficient removal of total cyanide the relative concentrations of ferrous and bisulfite ions are determined experimentally for each type of waste water. Typically, the concentrations of ferrous and bisulfite ions are ca. 100-200 ppm, but they may be higher or lower, depending upon the chemical characteristics of the waste water being treated.

Advantages of the Process over other Cyanide Removal Processes

1. Uses cheap, readily available industrial chemicals.
2. Total cyanide removal is rapid.
3. Minimal pH adjustment required.
4. Minimal production of solids, as total amount of added ferrous and bisulfite ions is small.
5. Process works in cold climates, near the freezing point of water.
6. Other ions (e.g. SCN^-) do NOT interfere (cf. chlorination, peroxide, ozone, etc., which react with SCN^-).
7. Removes ALL FORMS OF CYANIDE (free and complex metal cyanides). (cf. chlorination, peroxide, ozone, etc., which do not remove ferrocyanide, cuprocyanide, etc.).
8. Can be applied to batch operations or continuously flowing waste cyanide-containing streams.
9. Most importantly, no specialized equipment is required (often just a mixing tank and a settling tank are sufficient), and the process can be carried out by unskilled or semi-skilled operators.

Further Information

E.T.C., Inc. and Homestake Mining Company jointly own a United States patent on this process, and patents are pending in other countries.

The process is available for licensing to any interested companies or potential users. Technical assistance is available, to enable the process to be correctly adapted to each user's cyanide-containing waste water, in order to achieve optimum removal.

1068 Eden Bower Lane
Redwood City, California 94061, U.S.A.

Excess ferrous iron combines with the ferro-cyanide to form ferrous ferrocyanide.

$$2\ Fe^{II} + [Fe(CN)_6]^{4-} = Fe_2\ [Fe(CN)_6]$$

Some excess ferrous ions are oxidized by oxygen in the solution to yield a series of ferric ferrous cyanide complexes ultimately forming an almost insoluble precipitate Prussian Blue $Fe_4\ [Fe(CN)_6]_3$.

A very small amount of free cyanide (0.1 - 0.2 ppm) remains in equilibrium with ferrocyanide after the reaction with ferrous sulfate.

This remaining free cyanide reacts with excess ferrous bisulfite to form ammonium formeate which is non-toxic and in the ultimate alkaline solution decomposes to ammonia and is lost to the atmosphere (hopefully).

Step 4

Because the cyanide solution is so dilute, all the Prussian Blue does not precipitate even though it is very insoluble.

The pH is next raised from pH 4-5 to pH 8-8.5. This can be done using lime, caustic soda, soda ash, etc.

Ferrous hydroxide encapsulates the Prussian Blue which is now quantitatively precipitated. Any ferric ions present will also precipitate (at the lower pH) as ferric hydroxide which when nucleated on the Prussian Blue and flocculated with a small amount of Superfloc 127 are easily settled and filtered.

Any nickel, copper, zinc, etc. are present as anionic complexes and will be precipitated when the ferrous bisulfite is added in the presence of a little oxygen already in the solution.

Cupro cyanide + ferrous = Ferro-cupro-cyanide.

Nickel, zinc, chromium, cobalt, etc. all behave similarly and co-precipitate with the Prussian Blue.

Step 5

The precipitate is settled out in a settling tank from which the clear treated solution is decanted. Very small amounts of precipitate are formed and it can be allowed to accumulate for a long time without filtering.

It is claimed that by first forming Prussian Blue at a lower pH, a very large amount of the cyanide is removed early leaving a very much smaller amount to be decomposed. If the pH is high when the ferrous sulfate is added then ferrous hydroxide forms, which does not react with cyanide to form Prussian Blue.

At the low pH $SO_3^{=}$ is present as HSO_3^- in the presence of which Prussian Blue is formed. HSO_3^- is also necessary to decompose the residual cyanide to ammonium formeate.

The ETC-HMC process does not affect thiocyanate ions.

According to TRAUTMAN & OMMEN (1981) of Homestake Mining Co., the Prussian Blue pilot plant was difficult to operate and was very temperature dependent. During winter, the cold water temperatures resulted in a much slower reaction. Also, the effluent from the thickener after precipitation with ferrous hydroxide contained fine precipitated particles which required sand filtration. After sand filtration the Prussian Blue precipitation process reduced the total cyanide concentration to about 2.5 ppm. It is not known whether the ETC-HMC process has been modified or improved since the pilot operation was carried out.

REMOVAL OF IRON CYANIDES FROM WASTEWATER

The Prussian Blue process described above amounts to a method of converting cyanides to iron cyanide and precipitating them as a means of removing cyanide from solution.

Iron cyanides are often generated in gold recovery solutions and discharged with effluents. The toxicity of iron cyanides which, in themselves, have a very low solubility hangs on their instability in ultraviolet light. If present in shallow sundrenched streams, the concern is that under UV-light, the iron cyanides will decompose to release free cyanide.

TANIHARA, KOICHI, et al. (1983) described a process for "Treatment of Wastewater Coontaining Iron Cyanide Complexes: II - Precipitation and Removal of Iron Cyanide Complexes by Simultaneous Dosage of Zinc Sulfate and Sodium Thiosulfate." Government

Industrial Research Institute, Kyushu Kogyo Gijutsu Shikensho, Hokoku, Vol. 31, pp2005-2011, 1983 (Japanese).

CARO'S ACID - SALSIGNE

It has been learned that at the Salsigne gold mine in France, cyanidation is employed on a small scale. Salsigne effluents discharge to a trout stream.

Although no details were obtained, it is believed that cyanide is destroyed in their effluents by reaction with CARO's ACID (H_2SO_4 + H_2O_2). Apparently, it is not necessary to add an excess to the point of rendering the effluent acid. Details may be available from:

Telex: 500-465-F MINSIGN

Wet Air Oxidation

Wet air oxidation is now conventionally used in the U.S.A. for treatment of hazardous wastes and also sewage sludge oxidation. In all, about 250 plants have been installed.

One of these plants is installed in California to destroy cyanide at a hazardous waste site:

CASMALIA RESOURCES, INC.
Post Office Box E
Casmalia, CA 93429
(805) 937-8449
Al Brandt

The head office is in Santas Barbara and can be reached as follows:

CASMALIA RESOURCES, INC.
Post Office Box 5275
Santa Barbara, CA 93150
(805) 969-5897
Jim McBride
Technical Director
Ken Hunter
President

The small 10 gpm ZIMPRO Wet Air Oxidation Plant is used primarily to destroy cyanide wastes. No waste with over 100 ppm CN is allowed to be dumped at their hazardous waste site.

Wastes in excess of 100 ppm CN are detoxified in the ZIMPRO unit after which the wastes are considered detoxified sufficiently to be discarded.

Casmalia Resources tarif for cyanide detoxification starts at $120/ton so not too many gold operations could afford to take waste there, but this installation demonstrates that the method is in use.

Cyanide destruction requires 450°-500°F which equates to a pressure of 900-1,200 psig according to the vendors of this process who supply the design of the equipment:

ZIMPRO, Inc.
Military Road
Rothschild, WI 54474
(715) 359-7211
Al Wilhelmi
Bill Copa
Technical Director

A flowsheet of the ZIMPRO Wet Air Oxidation Process is inserted below. The process employs a stainless steel pressure tower or tube as the reactor.

According to ZIMPRO, the operating cost for these units is 1-2¢/gallon, i.e., $20-$40/1,000 gallons [$8-$16/m^3], which is relatively high. Of these costs, energy amounts to about $10/1,000 gallons ($2.50/m^3) for an effluent which contains no calorific value. If sewage is added, the oxidation thereof will contribute to the energy requirement. The major cost item is in pumping high pressure air into the system.

ZIMPRO WET Air Oxidation Units are capital intensive. For example, very rough ballpark estimates were provided as follows:

330 U.S. gpm - $10 Million
15-20 U.S. gpm - $2.5 Million

ZIMPRO, INC. is a subsidiary of Michigan Tech Ventures of Houghton, Michigan, which also offers a wet air oxidation process employing stirred reactors under the process name WETOX. Ontario Research Foundation in Mississauga, Ontario, is a licensee of this company.

Temperature achievable is, of course, a function of pressure applied, ranging as follows:

400°F - P=400-500 psig
450°F - P=900 psig
600°F - P=2,500-3,000 psig

Heat is recovered to preheat the feed. If excess heat is generated, it can be used as a source of steam.

GEOCLAVE OXIDATION

There are other innovative configurations of wet air oxidation reactors that have been installed on an experimental basis. In Colorado, two experimental geoclaves have been installed:

1) City of Longmont Geoclave

An EPA financed demonstration geoclave was in Longmont, Colorado, to test the combustion of sewage sludges and hazardous waste in a hole one mile deep. This geoclave requires 575°F to achieve an exothermic reaction, and it uses a G.E. heat exchanger to preheat feed material. These conditions would also decompose cyanide to CO_2 and ammonia.

The inner heat exchanger tube has a 5" diameter. The downcomer is 7" in diameter inside a 10" upcomer. Pressures of 1,500 psi are reached at a depth of 1 mile. Compressed air is injected at 40 ft. depth. The unit can handle 4-5 tons per day of solids and a volume reputed to be 120 U.S. gpm at 1% solids.

The Longmont geoclave is owned and operated by:

VERTECH TREATMENT CO.
Sub of Bow Valley Resource Services
2006 West 120 Avenue
Westminster, CO 80234
(303) 452-8800
Gerry Rappe

It is not known whether this geoclave has been tested for cyanide destruction.

2) Resource Technology Associates
11728 Highway 93
Boulder, CO 80303
(303) 499-1032
Dr. Mark A. Peters

This company constructed a test geoclave on the property of Hazen Research, Inc., Golden, Colorado. No details of test results have been released. It is not known whether it has been tested for cyanide destruction.

Conclusions on Wet Air Oxidation

1) To benefit from hydrostatic pressure, geoclaves must be very deep--3 to 5,000 feet. To contain corrosive fluids at high pressures and temperatures in such deep reactors means that large quantities of expensive exotic materials are required. This adds to the capital expense.

2) According to ZIMPRO, the operating costs of a wet air oxidation plant are small compared with capital cost items. A deep geoclave results in energy cost savings but increases the capital considerably. Therefore, it is unlikely that a geoclave will be less expensive overall than an above-ground reactor.

3) Operating costs of \$20-\$40 per 1,000 gallons (\$5-10/m^3) is high as far as effluent treatment for mine-mill effluents is concerned and, therefore, this technology does not appear to be attractive at this time for cyanide destruction, unless there already happened to be a wet air oxidation plant on site for sewage sludge oxidation which could combine the cyanide effluent in its feed.

ELECTROLYTIC CYANIDE DESTRUCTION

HSA Reactors Ltd's high surface area cathodes have been tested at the Pamour Schumacher Mill in Ontario as a means of destroying cyanide while recovering base metals. Cyanide is electro-oxidized to cyanate.

The desirable temperature of operation is about 60°C. The oxidation of cyanide is enhanced by the addition of salt to provide chloride ions. A metal stripping stage is also required to periodically remove the deposited metals. The metals may be recovered from the stripping solution by conventional electrolytic practice or by chemical precipitation.

MOHANTA et al (1980) submitted the following results of the pilot plant tests at the Pamour Schumacher mill to ENVIRONMENT CANADA:-

	Influent	Effluent
pH	11.7	9.8
Copper	450 mg/L	0.14 mg/L
Zinc	54	0.06
Total Cyanide	1300	2.8
Free Cyanide	733	0.3
Cyanate	72	1120
Thiocyanate	756	68
Sulphate	1625	2826
Chloride	1400	5400

HSA Reactors Ltd., claim that its process can destroy cyanide at about one-half the cost of that by alkaline chlorination, although RANDOL believes that at the extremely low cyanide levels, current efficiency might not be so good. However, the real merit in the electrochemical system stems from the possibility to recover cyanide by removing fouling metals when applied in a different way.

The HSA cyanide destruction process still requires further development to reach the anticipated regulatory-mandated levels but might present a cost effective first step for more concentrated effluents which could then be completed by chemical oxidation. It is noted in the case shown above, that cyanide seems to be converted to cyanate, the effect of which would have to be taken into account sooner or later. Meanwhile HSA Reactors Ltd. have gone out of business and are being liquidated.

Thiocyanates

According to a variety of sources, thiocyanates (CNS^-) are toxic to fish only at levels 1000-10,000 times higher than at which cyanide is lethal, i.e. 50-500 ppm CNS^-. More recent unconfirmed reports indicate that there may be cumulative toxicity problem associated with thiocyanate on fish. Some US tests have been talked about in which fish exposed to thiocyanate for an extended period had a low mortality rate until subjected to stress when there was a sudden high mortality. These tests were referred to in passing by Jim Kerrigan of AMAX ESI, Golden and by Jim Scott of Environment Canada, Hull, Quebec.

ENVIRONMENT CANADA, the EPA and State and Provincial Governments are evaluating the toxicity effects and whether and how CNS^- in mine and mill effluent discharges should be regulated, if at all.

In 1980, INTERNATIONAL ENVIRONMENTAL CONSULTANTS LTD. (IEC) undertook a literature review for ENVIRONMENT CANADA, on "The Fate of Thiocyanate in the Aquatic Environment". They concluded that thiocyanate is biologically degraded to sulfate, CO_2 and ammonia by several strains of bacteria. Unlike biodegradation of other sulfur containing species such as sulfide and thiosulfate, sulfuric acid is not a product. The bio-oxidation of thiocyanate is likely to be slow and no significant depletion of oxygen is expected to result from bio-decompostion of thiocyanates.

Photo-decompostion of thiocyanate is considered unlikely and little evidence of other chemical transformation of thiocyanate in nature were identified.

The IEC Report may be available from ENVIRONMENT CANADA (DSS Contract OSS79-00170) or possibly also from the author:-

(416) 236-1077

It has been shown that alkaline chlorination decomposes thiocyanate readily before it attacks cyanide. It is also found that the SO_2 processes do not attack thiocyanates. Peggy Layne of Raleigh, North Carolina, completed a M.Sc thesis on CNS^--destruction by ozone. She may be reached at:

PEGGY LAYNE
Hazen and Sawyer
Box 30428
Raleigh, NC 27622
(919) 782-8333

DAN KAPPES and DON BAKER (1981 personal communication) both cite instances where alkaline chlorination of thiocyanate rich effluents resulted in an increase in the measured cyanide levels.

Thiocyanates interfere with the standard total cyanide determination procedure which distills cyanide in the presence of sulfuric acid, but this interference has been overcome by a modification proposed by CONN (1981).

The bacterial decomposition of cyanides developed by Homestake is said to destroy thiocyanate as well. It is rumored that at Homestake, effluent CNS levels of up to 250 ppm CNS^- are experienced before treatment, but this also should be confirmed.

BYERLEY & ENNS (1982) have described a process whereby cyanide can be regenerated from thiocyanate. More information can be obtained from:-

WATERLOO CENTRE FOR PROCESS
DEVELOPMENT
University of Waterloo
Waterloo, Ontario N2L 3G1
E.B. Cross, Executive Director
J.J. Byerley
(519) 885-1211 Ext. 3300
Telex: (069) 55259

The process described by BYERLEY & ENNS (1982) employs an electrolytic cell about which not too many details have been released until the patent position is resolved. The cell employs bipolar electrodes and some form of preconcentration of CNS^- using ion exchange may be required.

At the Homestake mill, thiocyanate formation is symptomatic of cyanide consumption as a result of the presence of sulfides such as pyrrhotite in the ore. Homestake controls this phenomenon by judicious use of oxidation and pH control.

HALBE et al (1979) showed that cyanide consumption at Homestake goes up in summer, which has now been identified as being almost completely due to increased formation of thiocyanate. The rate of this reaction increases sharply above 10°C. Since tailings pond water at 20°C in summer is recycled to the process, a greatly increased cyanide consumption was observed compared with the earlier system in which fresh process water at 4°C was added to the system. Spray cooling was practised in 1978 with some success and the spray cooling was to be expanded in 1979.

Clearly, one way to reduce cyanide consumption and thiocyanate levels in tails is to leach pulps that generate CNS at a reduced temperature where possible.

CYANIDE RECOVERY

Cyanide recovery processes have been employed in the past and are likely to have greater potential applicability where ores with very high cyanide soluble copper must be treated, or where cyanide is very expensive such as in Peru where cyanide costs $3.00/kg.

With the growing number of CIP plants, the need for cyanide recovery appears to be growing since, contrary to the MERRILL-CROWE process where barrens containing cyanide can be returned for the most part to the leach circuit, only very limited cyanide can be recovered from CIP tailings pulp, since the whole point of using CIP is usually to avoid using a solid/liquid separation step in most cases.

In South Africa there is some concern that as more CIP plants come on-line, the overall cyanide demand will increase to the extent that an additional cyanide production facility will be needed which could result in a higher price for cyanide. Consequently, there is renewed interest in recovering cyanide from pulps. Clearly most of the processes tried before and outlined below, will be less likely to be viable for treatment of pulps than they were for solutions.

DORR & BOSQUI (1950) reviewed several techniques for cyanide recovery from barren solutions and foul liquors, which were also reviewed with inclusion of more recent pilot testwork on cyanide recovery by ion exchange by GILMORE & GOW (1963), which was inserted in Volume 2 (Phase I) of the Randol report "Innovations in Gold & Silver." More detailed information is provided by MCQUISTON & SHOEMAKER (1975).

These techniques and installations include:-

1) Mills-Crowe Process

Acidification to form HCN which is driven from solution by aeration and readsorbed in an alkaline solution in an absorption tower.

2) Regeneration at Pachuca, Mexico

Acidification of solution with SO_2 to neutralize lime and convert cyanides to HCN. Volatilizing HCN with a large volume of air. Absorption of HCN in mill solution. Zinc dust addition to precipitate gold in the pregnant solution after cyanide has been driven off.

SO_2 gas was made in a rotary sulfide burner and brought into contact with the cyanide solutions in an acidifier. HCN formed in the acidifier remains in the acid

solution until removed by air dispersion. It is remarkable that no measurable HCN was lost from the acidified solution as it passed through an open weir box 6' long.

3) Flin Flon Mine, Manitoba

Recovery of cyanide at the Flin Flon Mine of Hudson Bay Mining & Smelting, as described by DORR & BOSQUI (1950), for a plant treating 2814 tpd of barrens.

Again this process consists of acidification and volatilization of HCN by aeration in a dispersing tower. Airborn HCN was redissolved in an alkaline solution in an absorbing duct. A total of 36,000 ft^3 of air at 4" water pressure was required for the process.

Material balance was as follows:-

Barrens to Regeneration	2814 tons/day
Regenerable Cyanide (NaCN)	2.23 lb/ton
Lime	0.25 lb/ton
Tailings from Regeneration	
Regenerable Cyanide (NaCN)	0.18 lb/ton
Residual Sulfuric Acid	1.91 lb/ton
Sulfuric Acid Consumption	4.58 lb/ton barrens
Recovery of Regenerable Cyanide	91.5 %

4) Leaver & Woolf Process, USBM

This process demonstrated on a lab scale, involved regeneration of cyanide tied up in solution as complexes with zinc and copper in fouled mill solutions.

A soluble sulfide is added to the solution followed by acidification in a closed reactor to pH 5 or 6, whereby Cu & Zn sulfides precipitate and up to 80% of the combined cyanides are regenerated in the solution and can be recovered by filtration. Only after filtration is lime added to the filtrate to 'fix' the cyanide again.

5) Electrolytic Regeneration of Cyanide from Metallic Cyanide Complexes

Electrolytic removal of metallic impurities as a means of cyanide regeneration combined with recovery of the base metals were developed as a process but found uneconomical owing to the high cost of installation and operation, according to DORR & BOSQUI (1950).

Electrolytic recovery of cyanide from foul bleed solutions appears more promising in the light of new high surface area electrolytic cells available from HSA Reactors Ltd.

Reference to pilot testing of HSA Reactors equipment at Pamour Porcupine Mines Ltd. is made by INGLES & SCOTT (1981) inserted in this chapter.

Since the previously mentioned paper appeared, HSA reactors Ltd. have secured patent protection and are actively seeking applications for their well engineered equipment. More details on availability and cost as well as test facilities could be requested from HSA Reactors Ltd. except that they have recently gone out of business and are currently being liquidated by Canada Development Corporation. It is not yet known who will acquire the rights to the technology.

It is believed that the HSA electrolytic cell employed in the tests at the Pamour Shumacher mill was not able to liberate cyanide from iron cyanides or cobalt cyanide, but this should be confirmed.

6) Electrolytic Regeneration of Cyanide from Thiocyanates

BYERLEY & ENNS (1982) referred to above, have developed an electrolytic cell employing bipolar electrodes which regenerate thiocyanate to cyanide. More information is available from:-

J. J. BYERLEY
Waterloo Centre for Process Development
Waterloo, Ontario N2L 3G1
(519) 885-1211

7) Ion Exchange Resins

Several IX resins have been shown to adsorb cyanide and several new IX products have been developed since GOLDBLATT (1959) evaluated the possibility of recovering cyanide from gold mill wastes by ion exchange.

GILMORE (1976) again reviewed the subject, which was also tested on a pilot scale at the Homestake Mine in South Dakota. More information is summarized by INGLES & SCOTT (1981) inserted in this chapter.

The RANDOL investigation did not identify any operating plants employing IX for cyanide recovery.

GILMORE (1976) of CANMET used static columns to investigate the suitability of ion exchange on barren solutions from 6 gold mines. Adsorption was accomplished using two columns in series containing Amberlite IRA 400 resin. The resin was in the $SO_4^{=}$ form in both columns. Contrary to GOLDBLATT's (1959) findings, it was not necessary to condition the second column with cuprous cyanide.

Ind. Eng. Chem. 51, 241-6 (1959)

Recovery of Cyanide from Waste Cyanide Solutions by Ion Exchange Pilot Plant Studies

Pilot plant work has confirmed laboratory work showing that recovery of cyanide from gold mine effluents by ion exchange is economically attractive. This recovery was accomplished with poisoned, discarded anion exchange resin (IRA-400) from a uranium plant.

With effluents containing 0.10 to 0.16 pound of sodium cyanide per 100 Imperial gallons, recovery in the pilot plant was about 95%. At the same time the resin was purged of temporary poisons, and base metals which were formerly cyanide complexes were recovered.

Thus for a gold and uranium producer, a combined unit could recover cyanide, water, and base metals, and could also regenerate uranium plant resin.

ERIC GOLDBLATT
Stilfontein Gold Mining Co., Transvaal, Union of South Africa

Reprinted from INDUSTRIAL AND ENGINEERING CHEMISTRY, Vol. 51, Page 241, March 1959
Copyright 1959 by the American Chemical Society and reprinted by permission of the copyright owner

The first column was desorbed with 1% H_2SO_4 which decomposed the metal cyanide complexes. The barren then flowed through a cationic exchanger IRA 400 which adsorbed the metals, while the HCN passed through the column and was collected in a caustic trap. The recovered cyanide was available for reuse in the gold cyanidation step. The second absorption column was also desorbed with 1% H_2SO_4. The metals were desorbed from the cation exchange resin by a brine solution.

The results indicated that ion exchange can remove cyanide from barren solutions to below 0.1 mg/l.

8. MNR Regeneration/Recovery of Cyanide from Effluent

The cost of removing a pound of cyanide from effluents by destructive processes is generally much more expensive than adding apound of cyanide to a leach process. What this means is that every pound of cyanide added in excess of that really needed will contribute not only the wasted cost of that pound of reagent, but an even greater cost of removing it in a subsequent effluent treatment step.

Some effluents contain relatively high concentrations of cyanide--particularly barren bleeds from plants treating ores containing high concentrations of cyanide soluble base metals. For example, to leach gold using a cyanide solution containing soluble copper, cyanide must be added in excess of 5 moles CN^- per mole Cu^{++} to efficiently leach gold. If an ore contains excessive amounts of cyanidej-soluble copper, the cyanide requirement may be so high as to render the ore uneconomic. One such example is the Centinella Mine ore from Punitaqui, Chile.

BERGMAN, et al. (1984) described a new approach to cyanide recovery in the processing of this ore using a process piiot tested at Mountain States Mineral Development Laboratories, Tucson.

GEORGE M. POTTER
40 South Calcite
Tucson, AZ 85705
(602) 884-9609

At the University of Arizona conference on "Cyanide and the Environment," December, 1984, George Potter reported on this process which has been developed through pilot plant stages. He advised that the cyanide recovery cost amounted to about $1.00 per ton ore, i.e., about U.S. $0.10/Kg cyanide recovered, which is remarkable.

He also indicated that although a high recovery of cyanide is achieved, residual levels would still be high enough to require some form of treatment before the final effluent would be suitable for discharge as an effluent.

This promising development is described by BERGMANN, et al. (1984) below.

Abstract Regeneration of Cyanide - A Case Study

Pilot Cyanidation of a High-Copper

Gold Ore from Punitaqui, Chile

Dr. Arthur Bergmann, Armando Guzman, and George M. Potter

Complex high-copper gold ores may present serious processing problems. The treatment of a 0.45 percent copper, 3 to 5 gram per ton gold ore, and flotation mill tailings (0.42 percent copper and 1.66 grams gold), largely oxidized, from Punitaqui, Chile is a case in point. This paper describes intensive laboratory studies of cyanidation, flotation, acid-pre-leaching, and combination methods tried in an effort to find a feasible gold-copper recovery process. For various reasons, only direct cyanidation with abnormally high cyanide strength solutions and consumption of cyanide provided technically acceptable results, but cyanide costs were not tolerable. Therefore, a special cyanide regeneration process was applied on pilot scale to recover at least 95 percent of the total cyanides in the regeneration plant solution feed and at the same time remove and recover the copper. Pilot plant metals and cyanide balance data are given. The significant advantages of the regeneration plant operation in improving the process economy and reducing environmental hazards through removal of a heavy metal (copper) and complex and simple cyanides from wastes are noted.

2. Introduction

The recovery of gold and copper from complex ores by non-smelting methods may present serious economic and technical problems. As an example, the MNR Reprocessing, Inc. Centinela Project in Chile is a case study of the process investigation of gold-copper stored mill tailings and mine reserves requiring the development of cyanide regeneration process to provide technically acceptable results.

The Centinela Project comprises several deposits of old flotation mill tailings and unmined ore reserves within a 100-km radius of the town of Punitaqui, Coquimbo Province, Chile. The major tailing deposit contains 2.1 million dry metric tons at a grade of 1.66 grams of gold per ton and 0.42 percent copper. Unmined reserves in the area may exceed 1 million tons at a grade of 3 to 5 grams of gold per metric ton and 0.45 percent copper.

Intensive laboratory studies of cyanidation, froth flotation, acid pre-leaching to remove oxide copper, and combination methods were tried in an effort to find a feasible gold-copper recovery process. Non-cyanide leaching, such as by thiourea and hypo methods, was considered but not applied, because of potentially high process costs or lack of sufficient process development. Of the methods tried, only direct cyanidation with abnormally high cyanide leaching solution strength and free cyanide consumption provided technically acceptable results. Therefore, a special cyanide regeneration process was applied on a pilot scale to recover more than 95 percent of the total cyanides in the regeneration plant solution feed and at the same time remove and recover the copper in solution.

This paper is considered to be a progress report, inasmuch as detailed pilot studies designed to outline optimum regeneration process variables are still in progress. Regeneration process detailed descriptions, reagent consumptions, and operating data are therefore not being reported here, but are deferred to a later paper. Meanwhile, the pilot regeneration plant operations and performance have been consistent and reliable so that gold-copper metallurgical data pertaining to the Centinela Project together with quantitative cyanide regeneration information are presented in some detail under separate headings, following.

3. General

3.1 Location

The Centinela Project includes several deposits of stored flotation mill tailings and potential reserves of unmined vein ore, all containing gold and copper values. The Punitaqui area in Coquimbo Province lies from about 250 to 350 km north of the Chilean capital Santiago de Chile. A major seaport, Coquimbo, is about 100 km to the northwest. A large part of the potential

reserves is near the village of Punitaqui, which has an altitude of 200 to 300 m above sea level, and the climate is relatively mild. The area is served by paved roads from Santiago de Chile, its seaport Valparaiso, and the port of Coquimbo.

3.2 Geology

The several geological areas involved in the Centinela Project contain gneisses, phyllites, greenstones and a wide variety of marine and continental sediments of (questionable) Pre-Cambrian, Paleozoic, Mesozoic, and Cenozoic ages, intensively mineralized in connection with the Andean Batholith intrusion. Major and local faults are key factors in the mineralization, characteristically copper sulfides with varying gold and silver content.

4. Nature of Ore

4.1 Chemical	Au gm/T	% Cu	Ag gm/T
Old Flotation tailings (approx. 2.1 M tons)	1.66	0.42	1.0
Gold ore reserves (inferred, 1. M tons)	3 to 5	0.3 to 0.6	

4.2 History and Mineralogical-physical nature

The Punitaqui area has been sporadically active for more than 100 years in producing gold-copper ores. In 1956 the Empresa Nacional de Mineria installed a 500 tpd froth flotation plant to process ores from the region; however, the actual average production has been considerably less. The Minero Cerro de Centinela S.A. concern acquired the property from government-owned CORFU in June 1983.

The flotation mill tailing reserves have a physical screen analysis of 3 percent plus 200 micrometers and 50 percent minus 36 micrometers. Both tailings and mine ore contain gold too closely associated with hematite, copper and/or gangue to determine the mode of mineralogical occurrence. Copper is largely present in oxidized copper minerals in the mill tailings and in the presently known mine ore reserves. Carbonates are present in amount high enough to preclude an economical acid pre-leaching step for copper removal. Other constituent minerals are quartz, iron oxides, copper silicates, and silicate gangue. Copper is quite uniformly distributed through the mill tailing sizes, whereas the gold is slightly enriched in the finer sized fractions.

5. Laboratory test results

Extensive laboratory test work to determine the amenability of the various Centinela Project gold-copper old mill tailing deposits and newly mined ores was done. Various leaching methods and froth flotation (to recover gold and copper or remove acid consuming gangue prior to leaching) were tried. Preliminary process testing and development was done at the Metallgesellschaft AG Mining Division Laboratory, in Meggen, West Germany. Special processes such as pressure leaching, chlorine leaching, and others were tested by Lurgi Chemie und Hüttentechnik, Frankfurt am Main, West Germany. The Mountain States Research and Development, Tucson, Arizona provided confirmatory flotation and leaching tests and participated in the laboratory-scale and pilot cyanide regeneration investigations. The response of the tailing material and the mine ore were similar, although of course the mine ore was higher grade in gold and copper. Individual process test comments follow.

5.1 Froth Flotation

Froth flotation tests were conducted on mine ore assaying 11.5 grams of gold and 6.1 grams of silver per metric ton and 0.24 percent copper. About 67 percent of the gold, 21 percent of the silver, and only 6 percent of the copper in the ore were recovered in a cleaned concentrate assaying 465 grams of gold, 75 grams of silver and 0.8 percent Cu, and representing 1.7 percent of the original weight. The flotation feed size was 80 percent minus 150-mesh (tyler). Unfortunately, the flotation tailing still consumed exorbitant amounts of cyanide upon leaching.

Similarly, disappointing flotation results were obtained from stored mill tailings. The feed assayed about 1.7 grams of gold and 0.4 percent copper. By refloating the material without regrinding, the gold in the tailings was reduced to only about 1.5 grams at the lowest and always more than 0.3 percent copper in the form of easily leachable copper oxides.

In other tests, attempts to remove carbonates by flotation so as to permit acid leaching for copper removal prior to cyanidation were not successful. Subsequent acid leaching tests still exhibited consumption in excess of 100 kg of H_2SO_4 per metric ton.

5.2 Leaching

5.2.1 Agitation Cyanidation

Exhaustive agitation cyanidation testing of the Centinela stored old flotation mill tailings was carried out by the several laboratories. The usual parameters such as pH, time of agitation, percent solids in the slurry, strength of the cyanide solution, and amount of regrinding, if any, were carefully outlined. In summary, a gold recovery of about 85 percent of the feed content could be

attained without regrinding, or 90 percent with regrinding. From 40 to 50 percent of the copper in the material also dissolved. The pH was 10.5 with lime (CaO) and the percent solids 40 to 45, while agitation time of 24 hours appeared to be sufficient. The apparent consumption of free cyanide was very high, ranging from 3.0 to 8.0 kg of NaCN/metric ton in various parts of the tailing deposit. An unusual and very significant requirement was the very high initial concentration of free NaCN essential to obtain satisfactory recoveries; at 45 percent solids, 11.5 kg of NaCN per ton of ore addition was needed. Of the 11.5 kg free NaCN feed to the leaching system, only from about 3 to 8 kg per ton of ore remained as free NaCN after leaching. To emphasize the importance of the high cyanide concentration required for satisfactory leaching, a slide is presented showing in a curve the interdependence of gold recovery and cyanide concentration.

Cyanide agitation leaching tests were made on mine ore from accessible areas of the Punitaqui mine. The ore was ground to 200-mesh prior to testing. The results indicated that up to 91.5 percent of the gold could be recovered from 8 gram gold, 1.6 gram silver, 0.24 percent copper feed in 48 hours time. As in the case of the retreatment of the old tailings, very strong initial free NaCN solutions were needed (11.25 kg NaCN per ton of ore) and 4.6 kg of free cyanide was consumed per ton of ore. Lime usage was 1.6 kg of CaO.

5.2.2 Percolation cyanide leaching

Cyanide percolation leaching tests were made on samples of Centinela tailing material after careful agglomeration. Indicated extractions of gold were virtually as good as those obtained by agitation leaching. However, unusual difficulty was found in making pellets for percolation leaching. Even with 7.5 kg per ton each of lime and portland cement and curing, only marginally leachable pellets could be made. The commercial handling of such pellets from the point of physical degradation is in doubt.

The mine ore also responded to percolation cyanidation (heap) leaching tests. Ore crushed to 1/2" yielded 80 percent extraction of the gold and 45 percent of the copper after 26 days of leaching. The ongoing solution strength was 9.3 kg NaCN per ton of solution. Indicated consumption of free cyanide was 2.2 kg per ton of ore.

5.2.3 Other leaching methods

Pressure leaching

Pressure leaching in a tube reactor (Lurgi Company is a patent licensee) may provide the same recoveries as in atmospheric conventional leaching in shorter time and with lower reagent consumption. However, in the case of the very refractory Centinela material, cyanidation testing in the pressure system apparently did not provide metallurgical advantages, in that reagent consumption was about the same as in conventional methods.

Chlorine leaching

Chlorine leaching of the Centinela ores and old tailings was studied, with and without NaCl and CaO Cl_2 additions, but recoveries were slightly lower than cyanidation. No cost or process advantages were inferred, and further work was not done on this approach.

H_2SO_4 Pre-Leach

Leaching of the Centinela ores and materials with sulfuric acid to remove copper prior to cyanidation did have the effect of considerably lowering the subsequent cyanide consumption. Nevertheless, the consumption of sulfuric acid (H_2SO_4) ranged from 120 to 143 kg per ton of ore, and the overall cost of cyanide plus sulfuric was estimated to be more than that of straight cyanidation. Thus the approach was not continued.

Additional leaching methods

Other leaching methods were considered but not tried. They included the ammonium thiosulfate (hypo) system and thiourea leaching. Because these processes are still in somewhat of a developmental stage, they were not tried on Centinela materials at this time.

5.3 Gravity methods

Because of the fine grain size and complex mineralogical association of the gold at Centinela, gravity methods were not incorporated.

6. Discussion of metallurgical testing

Of all the metallurgical methods tried, direct cyanidation by either percolation (heap) leaching or slurry agitation leaching appeared to be technically most efficient and lowest cost. Even so, the high consumption of free cyanide and the need for adding unusually strong feed solutions created an anti-economical process, unless the cyanide could be feasibly regenerated. Therefore, efforts were directed to development of a suitable regeneration process. The requirements were to recover almost all of the free and complex cyanide in the leach liquor at a reasonable cost and at the same time remove and recover dissolved copper and perhaps other impurities (metals). Prior art and tests on the Centinela leach solutions and slurries indicated that gold (and silver) could be removed and recovered by (preferably) activated carbon processes from the solutions or slurries before the regeneration step.

7. Cyanide regeneration

7.1 Background

Historically, cyanide regeneration has been practiced for many years. For example, the Cia. Real del Monte y Pachuca (Pachuca, Mexico) still uses a regeneration process in operation since the 1920's. A similar process is described in the literature.[1] At Pachuca a Merrill-Crowe precipitation system barren solution is acidified in packed towers with SO_2 gas. The resulting HCN solution is sparged with large volumes of air, in packed towers, and the effluent HCN-bearing gases are reabsorbed in lime (CaO) solution also in towers, to reconstitute calcium cyanide solution.

A similar process at Flin Flon, Canada formerly operated.[2] However, sulfuric acid was used for acidulation, and the displacement of the HCN and readsorption took place in chambers equipped with mechanical rotors for gas-solution contact.

The Michigan Technological University and the White Pine Copper Company successfully collaborated on a process to cyanide-leach copper from White Pine ores, recover the copper, and regenerate the cyanide in a cyclic process.[3]

7.2 Laboratory-scale regeneration process development

A laboratory bench-scale prototype regeneration system was developed, studied, and modified prior to scale-up. The cyanide materials balance was obtained for the agitation leaching of tailings and is shown on the following page.

	NaCN kg per metric ton of ore
NaCN added to leaching	11.25
Free NaCN in leach effluent, and	6.35
Complexed cyanide in leach effluent	4.70
Total free and complex cyanide in effluent	11.05
Cyanide content in solid tails	0.20
Free cyanide content after regeneration (97.5%)	10.57
Other (CN) in regenerated solution	.08
Unaccounted for (largely in safety scrubber)	0.40

These encouraging results led to the development of a pilot regeneration plant as described in a following section.

8. Pilot-scale tests and regeneration

8.1 Pilot regeneration plant

Based upon encouraging bench-scale regeneration tests and cyanide leaching tests of Centinela ores and products, a 5 gpm pilot cyanide regeneration plant was constructed at the Tucson facilities of Mountain States Research and Development. The plant incorporates the following essential stages:

- Storage of cyanide leaching pregnant solution to provide accurate accountability and steady flow to the plant.
- Extraction of gold and silver from the pregnant solution in a series of 5 expanded-bed activated carbon columns.
- Addition of reagents to the effluent solution from carbon columns.
- Thorough mixing of solution and reagents.
- Careful control of physical and chemical parameters.
- Removal by filtration of copper (and certain other heavy metals) that might be present.

-Adjustment of solution by addition of any necessary alkali (typically lime) and cyanide (usually NaCN) prior to reuse in the leaching cycle.

-A completely sealed system further monitored by electronic cyanide detectors interlocked with certain controls, to provide safe operation.

Depending upon conditions, testing of the pilot unit indicated that from 90 to 99.7 percent of the total cyanide fed to the plant was recovered as a suitable free cyanide solution for reuse in leaching. Copper recovery from the plant feed was as high as 98 percent of the feed solution content.

8.2 Pilot simulated heap leaching and regeneration

To provide suitable solution for further regeneration pilot tests and also confirm percolation cyanide leaching response of Centinela mine ore, an 18.1 metric ton column leaching test was made. A sample assaying 4.39 grams of gold, 2.40 grams of silver, and 0.95 percent copper was crushed to 21 percent plus 4 mesh and agglomerated with 1.5 kg/MT $Ca(OH)_2$ at 10 percent moisture in preparation for leaching. After 26 days of leaching and 3 days of draining and washing, gold recovery was 80.4 percent, silver 28.1, and copper 45.0. The estimated process loss of cyanide in the heap leaching and regeneration steps totaled 1.5 kg NaCN per metric ton of ore treated; this loss might be decreased by better washing. Metallurgical data for the subsequent regeneration plant operation are presented in Table 1, Metallurgical Data, Regeneration.

Regenerated cyanide solution was made up to 9.19 kg NaCN per metric ton strength by adding 1.19 kg/T NaCN and used to leach duplicate 1-ton samples of Centinela ore. The leaching recoveries were fully as good as if fresh NaCN solutions were used.

The data presented in Table 1 indicate that about 99.7 percent of the total cyanide (both free and complex) was recovered in regenerated free form as a combined solution containing the regeneration solution, gas scrubber solution, and filter wash. The copper product contained more than 99 percent of the original regeneration plant feed solution content and assayed 60.3 percent copper (dry basis).

The considerable dilution evident in the combined regeneration plant solution products is expected to be reduced markedly in longer continuous runs in practice. However, in order to maintain strict solution balance conditions in a cyclic leaching and regeneration circuit, an accessory conventional HCN sparging and reabsorption system has now been added to the pilot unit to treat a small part of the regeneration plant flow, as necessary to avoid any net dilution.

9. Conclusions and Discussion

Laboratory and experimental pilot leaching investigations show that the Punitaqui ores and old stored tailings tested respond well to cyanide leaching provided that an unusually high concentration of free cyanide on the order of 9 to 12 kg of NaCN per metric ton of leaching solution is used. The gold and silver dissolved are readily recovered in active carbon. Gold recoveries on the order of 85 percent from tailings and 90 percent from ores were achieved.

9.1 General

From the laboratory bench scale and pilot studies of the regeneration process under investigation, it was concluded that the system reliably removes and recovers heavy metals such as copper from the Centinela Project high-copper cyanide leaching pregnant solutions, following recovery of gold in active carbon. At the same time cyanide (both free and complex) in Centinela solutions largely reports in a regenerated solution form suitable for recycling to the leaching process.

9.2 Environment

The regeneration process studied is foreseen to have a favorable impact upon environmental operational factors as well as on the economy of treating gold-copper ores and products such as the Centinela. All of the water in the entire process except for moisture content of the final tailing is planned to be recycled. Inasmuch as soluble heavy metals cyanides (such as copper) are not recycled back to the ore leaching stage, waste solids should be relatively low in these compounds. Evidently there would be no extra process costs because of the neutralization of various waste liquids.

10. Future Work

Although reliable and consistent results have been achieved in process studies to date, "fine tuning" investigations to optimize reagent and other process variables continue. Thus, process details are being reserved for a subsequent report.

Study of the potential application of the process to a variety of other ores and products has been initiated.

Preliminary capital and operating cost estimates (U.S.A. basis) are under preparation, and if available in time will be discussed at this presentation period.

Recovery of Cyanide from Waste Cyanide Solutions by Ion Exchange

Pilot Plant Studies

ERIC GOLDBLATT
Stilfontein Gold Mining Co., Transvaal, Union of South Africa

This system achieves the ultimate in efficient, economical plant operation. Permanently fouled ion exchange resin, which would otherwise be discarded from the uranium plant, is used to recover cyanide, water, and complexed base metals from the effluent of the gold works. Furthermore, this same effluent can substitute for caustic soda in removing temporary poisons from the uranium plant and thus reduce operational costs

Laboratory work at Stilfontein (*6*) has shown the feasibility of applying ion exchange for the recovery of cyanide from waste cyanide effluents, particularly those of the gold mining industry. The results were sufficiently encouraging to warrant further investigation on a pilot plant scale. However, until recently certain aspects of the investigation could not be disclosed for reasons of security under the South African Atomic Energy Act.

In 1954 the Stilfontein Gold Mining Co. became a joint uranium producer with several other smaller mines which pumped their ore pulp to the Stilfontein uranium plant for treatment (*7*). With the pulp there was a considerable amount of solution containing cyanide which had to be combined with Stilfontein's cyanide waste solution, complexed with iron(II) sulfate, and disposed of along with the pulp residue. Not only was there a loss of potentially recoverable cyanide with the additional expense of its neutralization, but also a loss of 500,000 gallons of water daily. It was the unsatisfactory economics of such a combined loss that initiated the original investigation into cyanide recovery by the use of ion exchange resins.

The recovery and concentration of uranium at Stilfontein requires the use of a strong base ion exchange resin (Rohm & Haas Amberlite IRA-400). While resin is in the uranium plant, its capacity for uranium is considerably reduced by the presence of certain compounds in the leach liquor from which the uranium is extracted which are poisonous to strong base anion exchange resins. Some of these poisons are temporary, such as silica and the polythionates which can be removed by a 5% caustic soda regenerant.

Figure 1. Free cyanide from the primary column effluent is complexed with deliberately precipitated copper(I) cyanide in the conditioned columns (S_1 and S_2), and effluent from them can then be returned to the gold plant as comparatively fresh water

Figure 2. Adsorption of the primary column (as shown by these typical curves) is complete when thiocyanate in the effluent begins to drop with an accompanying increase in cyanide

Influent, 0.0010 pound of sodium cyanide and 0.0009 pound of sodium thiocyanate per gallon

However, one of the cobalt cyanide complexes, derived from the acidification of the original cyanided ore pulp, is a permanent poison to the resin (*3, 8*). Over a period of two years the resin's capacity for uranium is so reduced by gradual build-up of the cobalt complex that its further use in the plant is uneconomical and a large quantity of used resin becomes available for other uses.

Recovery Process

The pilot plant studies on cyanide recovery are based on work carried out on the used resin from the uranium plant. In compliance with gold plant practice, all references to cyanide, whether complexed or free, are sodium cyanide as NaCN. In addition, all gallons are in Imperial units, and weights are avoirdupois including that of gold.

The principle of ion exchange cyanide recovery is to absorb the metal cyanide complexes present in gold plant waste cyanide solution (Table I) on a column of the strong base anion exchange resin in the sulfate form. The effluent from this column is then passed to another column of similar dimensions where free cyanide is complexed with copper(I) cyanide that has deliberately been precipitated within the second columns' resin beads. A column of resin containing precipitated copper(I) cyanide is referred to as being "conditioned."

Effluent from this second column, which contains thiocyanate and carbonate anions but is otherwise free of deleterious substances, can be returned to the plant as comparatively fresh water.

The columns are eluted with 1.0% sulfuric acid solution which decomposes the metal complexes in the first column and the copper cyanide complex in the second conditioned column. During elution of the first column, the eluate containing various metal sulfates and hydrocyanic acid is passed directly through a column of cationic resin of the sulfonic acid type (Rohm & Haas IR-120) in the sodium form to remove metal ions. The eluate, free of metal ions, is then suitable for re-use in the gold plant.

If it is necessary to increase cyanide concentration further, the eluate is reacidified to its former 1.0% sulfuric acid strength and used to eluate the second copper(I) cyanide conditioned column. In the latter instance it is not necessary to pass the eluate again through the cation column, as copper(I) cyanide from the breakdown of the copper complex is reprecipitated within the resin beads.

Metals are eluted from the cation column by a 10% sodium chloride solution.

Table I. Composition of Waste Cyanide Solution from the Gold Reduction Plant

Components	Lb./100 Gal.
NaCN (total)	0.10–0.16
NaCNS	0.07–0.10
Zn	0.01–0.03
Ni	0.001–0.015
Cu	0.001–0.010
Co	0.0001–0.001
Au	0.00001–0.00004

Pilot Plant Construction

Columns for the pilot plant (Figure 1) were constructed from 17.5-inch rubber-lined piping and were 6.0 feet long, with 0.75-inch stainless steel outlets attached to the top and bottom rubber lined plates. These in turn were bolted to the flanges of the columns.

Inside each column over the bottom outlet, was a perforated, 4-inch-diameter plastic disk mounted on 0.25-inch legs so that a free flow of solution was achieved through and around its sides. The disk and the bottom of each column were covered to a depth of 3 inches with 1-inch stones, 3 inches with 0.5-inch stones, 3 inches with fine-screened gravel, and finally resin to a depth of 24 inches.

The fresh and used acid tanks had a capacity of 500 gallons each, and the 10% sodium chloride and concentrated cyanide tanks were of 200-gallon capacity. All tanks were rubber lined, with 0.75-inch stainless steel outlets at the base. Both the fresh and used acid tanks were sealed, except for U-trap vents at the top of each which contained a lime slurry to prevent loss of hydrogen cyanide by evaporation from the acidified contents.

Columns and tanks were interconnected with 0.5-inch polythene tubing. Elbows, T-pieces, and diaphragm valve connectors were of 0.5-inch Kralastic piping. Saunders diaphragm 0.5-inch valves of mild steel were used with the columns and tanks when 1.0% sulfuric acid was used. Diaphragm valves on the cation column, sodium chloride tank, and pump were Saunders plastic 0.5-inch valves.

Gorman-Rupp Mansfield Line 8B12 pumps were used for pumping sulfuric acid and sodium chloride eluriants. Each of the primary (P_1 and P_2) and secondary (S_1 and S_2) columns were loaded with used IRA-400 resin from the uranium plant; fresh IR-120 was used in the cation column. The resin depth of 24 inches allowed a volume of 3.3 cubic feet of resin or 20.6 gallons for each column. Adsorption flow rate was 3.5 gallons per minute (0.17 bed volume per minute); elution flow rate, which was also the adsorption flow rate of the cation column, was 1.0 gallon per minute (0.05 bed volume per minute).

Conditioning. Maximum conditioning of secondary columns S_1 and S_2 was achieved by the following procedure: Commercial copper sulfate was dissolved in water to give an approximately 2.5% solution, and a strong solution of commercial caustic soda was added to precipitate the hydroxide. The addition of caustic soda was continued until the cambridge-blue precipitate just turned to a deeper or oxford-blue color.

A strong solution of sodium cyanide was then added until the precipitate

Figure 3. Elution of cyanide from primary column with 1.0% sulfuric acid

Effluent is passed directly to cation exchange column to remove metallic ions

Figure 4. Elution of cyanide from secondary column with 1.0% sulfuric acid

First portion of effluent returned to gold plant. Second portion recycled to used and fresh elute tanks

dissolved. The cuprocyanide solution (approximately 30 gallons) was then pumped into a secondary column and allowed to percolate very slowly through the resin bed for a period of 12 to 18 hours.

The bed was then thoroughly washed with water and eluted with 1.0% sulfuric acid solution until the cyanide concentration of the eluate dropped to less than 1.0 gram per liter of sodium cyanide. The column, after washing by downflow, was ready for adsorption of free cyanide.

Plant Operational Procedure

The main objects of the investigation with the pilot plant were to recover and concentrate cyanide by ion exchange and to achieve this by the use of the uranium-plant used resin (Amberlite IRA-400). Procedure for operating this pilot plant was based on a previous report which continued a step by step procedure for continuous operation (*6*).

Adsorption curves determined with the pilot plant for the primary and secondary columns follow closely those obtained on the laboratory columns; Figure 2 illustrates the adsorption curve for a primary column. Exhaustion of the primary column was estimated to be complete when the thiocyanate content of the effluent began to drop with a corresponding increase of cyanide. This was an indication that the column was saturated with complexes, and thiocyanate was beginning to pass straight through the resin bed. Completion of a secondary column adsorption cycle was taken on the first trace of cyanide breakthrough.

In the original laboratory work, nickel was evident in the primary column effluent throughout the adsorption cycle. Since then the Stilfontein plant has adopted a fairly large water wash for its pulp filters, resulting in a higher dilution of the waste cyanide solution than previously experienced. At this lower concentration, nickel cyanide is completely adsorbed by the resin and only appears in the effluent when the resin bed is almost saturated with the metal complexes. Therefore, as a rapid means of determining column exhaustion it has been found preferable to estimate a spot test (*5*) the completion of the adsorption cycle by the appearance of nickel in the effluent.

Elution curves with 1.0% sulfuric acid are shown for the primary and secondary columns (Figures 3 and 4). As the eluates from the primary columns were passed directly into the cation resin column to prevent metals entering the used acid tank, a further curve (Figure 5) shows the eluate after passage through the cation column.

One cation resin column of 3.3 cubic feet of IR-120 had sufficient capacity for metals from the elution of two primary columns. Therefore, for calculation purposes, a "run" includes the adsorption and elution of two primary columns, one secondary column cycle that may have taken place during that period, and one cation column adsorption and elution cycle (Table II).

For studying the economics of the cyanide recovery process, it had been decided originally that metals adsorbed by the cation column were waste products to be removed from the column as economically as possible.

Elution of the cation column by the

Figure 5. Primary column eluate after passage through cation exchange column

First portion of cyanide bearing effluent returned to used acid tank. Second portion is returned to fresh acid tank

Figure 6. This primary column is fouled with copper(I) cyanide, and free cyanide breakthrough is delayed because of complexing as in a conditioned column. Treatment with iron(III) sulfate regenerates the primary column

conventional methods with 10% sodium chloride elutriant would not only require operational procedure equivalent to the rest of the pilot plant alone but also the quantity of elutriant to ensure maximum recovery would prove expensive. Therefore, a method similar to that used for regenerating resin columns for chromium recovery from plating solution was adopted (7). The cation column, upon exhaustion after the passage of the eluates from the two primary column elutions, was not required for a further 30 hours or so. Consequently, this period of time allowed a prolonged contact of elutriant with the resin.

Cation Column Elution. The column was drained of superfluous liquid equivalent to the volume above the resin bed, replaced with 30 gallons of 10% sodium chloride solution, and a further 10 gallons of column liquor was removed. The resin was allowed to stand overnight in contact with the brine solution, and on the following day it was slowly drained to waste.

Such lengthy contact time of the sodium chloride elutriant with the loaded resin effectively removed most of the metals with a minimum use of regenerant. The resin, after backwashing thoroughly with water, was prepared for the next cycle by draining the column until only six inches of water remained above the level of the resin bed.

Eluate Distribution. From the elution curves (Figures 4 and 5), the following procedure was adopted for the eluate distribution from the primary and secondary columns.

Primary Columns (from Figure 5)

Source	Gallons	Bed Vol.	Destination
Fresh acid tank	40	1.9	Waste
	200	9.7	Used acid tank via cation column
	220	10.7	Return to fresh acid tank
Water	120	5.8	Fresh acid tank
Total	380		

Figure 5 shows that water to fresh acid tank is quite high in acid because of the removal of bisulfate ion from the resin bed. This leaves most of the resin in the sulfate form, which at the same time recovers acid (2).

Secondary Columns (from Figure 4)

Source	Gallons	Bed Vol.	Destination
Used acid tank	40	1.9	Waste
	90	4.4	Concd. cyanide tank
	20	1.0	Return to used acid tank
Water	110	5.3	Fresh acid tank
Total	260		

As with elution of the primary column, acid recovery was high because of the removal of the bisulfate ion from the resin.

The above procedure does not allow for a complete solution balance, and

Table II. Cyanide Recovery

Resin capacity was lowered by the presence of copper(I) cyanide

Run No.	Influent, Gal.	Total NaCN Available, Lb.	NaCN Eluted per Run, Lb. P_1	P_2	S_1	S_2	Total NaCN Recovered, Lb.

29	21,420	29.4	11.6	11.0	...	...	22.6
30	17,850	24.0	10.9	10.5	6.0	...	27.4
31	15,540	20.7	10.0	9.0	...	5.9	24.9
		P_1 and P_2 regenerated with $Fe_2(SO_4)_3$					
32	32,970	35.3	13.4	13.0	6.2	...	32.6
33	27,500	31.0	12.0	12.0	...	5.9	30.3
34	20,000	28.1	10.5	13.8	5.8	...	30.1
35	20,580	32.3	10.7	14.0	...	5.9	30.6
36	19,000	33.1	12.1	14.3	6.2	...	32.6

contents of the used acid tank tended to build-up. This was alleviated by using, on occasions, a portion of the used acid for elution of the primary columns.

Source	Gallons	Rel Vol.	Destination
Used acid tank	40	1.9	Waste
	180	8.7	Concd. cyanide tank via cation column
	40	1.9	Return to used acid tank via cation column
Fresh acid tank	200	9.7	Return to fresh acid tank
Water	120	5.8	Fresh acid tank
Total	580		

Obviously, the procedure can be somewhat elastic in operation; this was most desirable as the distribution of the eluate was dependent on the amount of complexed and free cyanide in the gold plant effluent, which varied considerably. Therefore, to avoid build-up of solution in the used acid tank, the elution procedure was varied to suit conditions.

Depending on the amount of the nickel complex adsorbed on a primary column, some of the nickel cyanide was incompletely decomposed by the eluriant. However, back-elution with the last 200 gallons of fresh acid in the latter half of the elution cycle removed most of the residual nickel from the resin bed.

Cyanide Recovery

The majority of the cyanide recovered from the waste cyanide solution was that which had been complexed with the zinc, nickel, and copper. Practically all the cyanide was recovered from the decomposition of zinc and nickel but only a portion from the copper complex according to the following equation:

$$2R_4[Cu(CN)_4] + 3H_2SO_4 \rightarrow 2CuCN + 6HCN + 3R_2SO_4 \quad (1)$$

Therefore, after each adsorption and elution cycle more copper remained behind as copper(I) cyanide, until the resin was so fouled that only about a third of the other metal complexes were adsorbed. Figure 6 shows how free cyanide breakthrough had been delayed because of complexing with copper(I) cyanide in a manner similar to a conditioning column, to be followed shortly after by the zinc and nickel breakthrough. This resulted in a lowering of capacity as shown by the eluted columns for runs 27 to 31 of primary columns P_1 and P_2 in Table II.

However, copper(I) cyanide fouling the primary columns could be readily removed by treating the column with a strong solution of iron(III) sulfate, very much in the same manner as the cation column is eluted of the metals by sodium chloride solution. The reaction between insoluble copper(I) cyanide and iron(III) sulfate (*7*) is illustrated by Equation 2.

$$Fe_2(SO_4)_3 + 2CuCN \rightarrow 2FeSO_4 + Cu_2SO_4 + (CN)_2 \quad (2)$$

As the Stilfontein Uranium Plant uses the acid leach process, large quantities of waste dilute iron(III) sulfate solution [0.4% iron(III) ion] are available. This dilute iron(III) sulfate has been very effective for removing copper(I) cyanide by passing the solution through a column for a period of 12 hours at 3 to 4 gallons per minute. A thorough wash with water prepares the column for the next cycle.

Alternatively, a 10% solution of sodium cyanide removes copper(I) cyanide. The copper in the sodium cyanide eluate is removed by acidification to precipitate copper(I) cyanide, and the clear cyanide solution is decanted off and then made alkaline for re-use.

The number of runs obtained before the primary columns required regeneration by iron(III) sulfate varied from five to 11, depending on the amount of copper present in the waste cyanide solution. Comparison of the two series of runs in Table II shows that fouling was greater in the runs 27 to 31. The secondary conditioned column capacities remained constant maintained throughout six months' operation. No doubt some copper was lost from the secondaries during each elution, but it was replaced by the small leakage of copper complex which unavoidably occurred on occasions from the primary columns.

Water and Gold Recovery

At the same time that cyanide was recovered, water and gold was also recovered (Table III). The amount of water available for re-use in the gold plant would be theoretically equivalent to the influent introduced into a cyanide regeneration plant. By the time it emerges as the effluent it is comparatively free of deleterious substances, except for thiocyanate which is not known to be actively poisonous to gold precipitation. Nevertheless, it would be advisable to dispose of a quarter of the effluent to avoid too great a build-up of the thiocyanate in what would amount to a closed circuit between any proposed cyanide recovery unit and the gold plant (Table III).

The gold cyanide complex is not adsorbed to any great extent by the strong base resin in the presence of other metal cyanide complexes. Once the resin is saturated with respect to gold, leakage of gold will take place. The extent of gold leakage from the resin is a function of the composition of the influent solution. In the event of a closed circuit between cyanide recovery unit and gold plant, this leakage would be returned to the gold plant where this gold would be eventually recovered. In some instances effluent gold concentration was actually higher than influent concentration (Table III).

If fresh resin is used, the appearance of gold in the effluent is delayed for some time until equilibrium is reached, but with used resin from the uranium plant, where there has already been a considerable amount of gold adsorbed on the resin (amounting in some cases to as much as 0.45 ounce per cubic foot of wet settled resin) breakthrough

31	24.9	0.025	11,655	40.02	30	850	30*
Total	136.6	0.343	86,468	242.24	150	2,957	30

* The iron(III) sulfate consumed in run 31. This reagent needed once each 5 to 11 runs.

is immediate. In practice the amount of gold present on the resin before self elution begins to take place is approximately 0.35 ounce of gold per cubic foot.

From the given five runs 27 to 31, Table IV has been constructed for calculating the economics of reagent consumption under the poorest conditions for cyanide, gold, and water recovery. No attempt has been made to convert the economics to a cash basis as prices for materials in South Africa are different from those elsewhere. For instance, water recovery is an important factor in South African plant economics as the price charged to Stilfontein amounts to one shilling per thousand gallons [14 cents (U.S.A.) per 1000 Imperial gallons].

For ease of comparison however, the totaled values of Table IV have been converted to equivalents of recovery and consumption to 1.0 pound of sodium cyanide recovered as follows:

Recovered	Reagents Consumed
1.0 lb. NaCN	1.77 lb. H_2SO_4
0.0025 oz. Au	1.0 lb. NaCl
633 gal. H_2O	21.65 gal. H_2O
	0.22 lb. $Fe_2(SO_4)_3$

Under South African milling conditions and using uranium plant discarded resin, this would appear economically attractive for the treatment of 10 to 11 million gallons of gold plant effluent at present available from the Stilfontein gold plant each month.

Base Metal Solution Balance

The amount of zinc and nickel recovered as concentrates in the sodium eluate from the cation column is also given here. This should not be, at least for Stilfontein, construed in any way as a contribution to the lowering of operating costs.

Table V gives the balance for zinc and nickel, and there appear to be possibilities, after applying conventional chemical practices to the zinc-nickel-brine solution, of proving concentrates of each metal salt, with recovery of sodium chloride, sufficiently attractive for future application.

Table V. Zinc and Nickel Recovery Data Show Possibilities for Providing Concentrates of Each Metal Salt

30 gallons of 10% sodium chloride cation column eluriant was used for each run

Run No.	Metal Available for Recovery, Lb. Zn	Metal Available for Recovery, Lb. Ni	Metal Recovered, Lb. Zn	Metal Recovered, Lb. Ni
27	5.02	2.12	4.95	1.90
28	4.10	1.70	3.80	0.88
29	3.50	1.20	3.00	1.04
30	3.00	1.10	2.70	1.00
31	2.80	1.40	2.50	1.00

Contrary to expectation, cobalt as the cyanide complex did not pose any problems. Although the amount of cobalt in the effluent was less than that in the influent (0.00006% as compared with 0.00010%), this was balanced by amounts of cobalt found in the eluates and water washes. Analysis of the resin after several runs indicated no increase in cobalt content. Thus, the cobalticyanide complex found in the gold plant alkaline solution is not the same as that found in the ore pulp after acidification, and therefore it is not held so tenaciously by the resin exchange sites.

Resin Regeneration by Waste Cyanide Solution

During the investigation a considerable number of resin analyses were carried out to determine what effect the gold plant effluent had on the used resin itself. What was particularly noticeable was the resin beads regained their original color and appearance after one run and temporary poisons such as silica and polythionates adsorbed on the resin from the uranium pregnant solution had been almost entirely removed.

This immediately suggested the possibility of using the waste cyanide solution with its alkalinity of pH 11.0, as a regenerant in place of the somewhat expensive caustic soda at present used. Not only could a cyanide regeneration plant be used for cyanide recovery, but a double purpose would be achieved by regenerating the resin at the same time in the primary columns.

As this could be immediately applied in the plant, experiments were undertaken on the uranium plant itself, where gold plant effluent was led directly into a set of three uranium columns containing 200 cubic feet of IRA-400 each. Analysis of the resin before and after treatment is shown by Table VI, where percentage removal of silica and polythionates with 5% caustic soda is also compared. It is estimated that by using gold plant waste cyanide solution instead of caustic soda as a regenerant, there would be a saving of £5000 per annum to the Stilfontein uranium plant.

Table VI. Comparison of Waste Cyanide and 5.0% Caustic Soda for Regeneration of Uranium Plant Resin

Use of waste cyanide solution would result in a considerable saving

Regenerant	Removed, % Silica	Total sulfate	Polythionates	Cobalt
Waste cyanide	75.0	62.4	81.3	0.4
5% NaOH	96.3	21.2	30.0	Nil

Personnel Requirement

Because of the long adsorption times, only one skilled and one unskilled operator working a morning or afternoon shift and alternating weekends are all that would be required to operate manually the adsorptions and elutions of a full plant with a capacity for 3,000,000 gallons of waste cyanide solution daily.

Conclusions

Experimental work with the pilot plant has confirmed expectations for a satisfactory economical process to recover cyanide, water, and gold from the effluent of a gold reduction works by the use of a strong base ion exchange resin. In addition the resin formerly used in the uranium plant and discarded has been found suitable for use in the cyanide recovery process.

The gold plant effluent also exhibits a cleansing action on the uranium plant resin, in some respects superior to that of caustic soda used at present as a regenerant for removing temporary poisons from the resin. Therefore, any large plant for operation at Stilfontein will be designed so as to achieve the double purpose of recovering cyanide and regenerating resin for the uranium plant.

Acknowledgment

L. A. Krige assisted both on the original laboratory work and the present pilot plant, and F. X. McGarvey of the Rohm & Haas Co. reviewed and read proof in the U. S. The manager of Stilfontein Gold Mining Co., Ltd., and the consulting engineer, General Milling and Finance Corp., gave permission to publish this paper.

SUBJECT Cyanide and Activated Carbon

Here is the story on cyanide destruction with activated carbon as recalled to me by the Calgon man that did the work in the 1970's. Calgon received a patent on the process.

Granular carbon will promote air oxidation of cyanide to cyanate very effectively. Cyanate is about 1/200th as toxic as cyanide. But to destroy the cyanate and go all the way to NH_3 and CO_2 a catalyst is needed. Calgon used copper sulfate at about the same concentration as cyanide. The reaction products then hydrolyze as follows:

$$KCNO + 4\ H_2O \rightarrow KOH + NH_4OH + H_2CO_3$$

where upon these products reacted with the copper in solution to form

$$Cu\ (OH)_2 \bullet CaCO_3$$

which set-up like a blue cement in the carbon column. They didn't find a way to circumvent the problem at the pilot plant stage.

I understand that the E.L. Bateman Company of South Africa is promoting a cyanide recovery technique involving carbon.

I'm guessing as to the overall mechanism. Its possibly an adsorption of the cyanide complex followed by acidification of the carbon to release HCN and then caustic scrubbing to produce NaCN. I don't believe anyone is using the process commercially, but its also relatively recent development.

9) Carbon Adsorption of Cyanide

There is some talk of using carbon to recover cyanide from solution and even CIP tailings pulps. Since cyanide is destroyed by carbon in the CIP process especially at a reduced pH in the presence of copper ions, it remains to be seen just how such a process will work.

Carbon adsorbs species as ion pairs according to DR. RAY DAVIDSON of AARL and DR. GLORIA MCDOUGALL of Sentrachem Ltd. For good adsorption, the ionic charges on these pairs should be balanced. That is AuCN and CuCN will adsorb much more readily than $Au(CN)_3^{-2}$ or $Cu(CN)_3^{-2}$ for example. Iron cyanide complexes usually contain a large amount of cyanide per unit of iron because of the large number of cyanide ions around an ion atom - e.g. $Fe(CN)_6^{-4}$. However, since $Fe(CN)_6^{-4}$ has four negative charges, it probably would not load well. However, it is possible that species such as Prussian Blue might well be made to adsorb on carbon. Conceptually such species could possibly be eluted again to regenerate cyanide by changing the pH for example to drive off some cyanide rendering the species charged again, but this would have to be established. Bateman Uranium Corporation is reputed to be offering a process for cyanide recovery from pulps using a specially treated carbon. Details of their process were not revealed. Meanwhile, mining companies can probably get some information from:-

OCCURRENCE OF F^-

Fluoride occurs in the groundwater supply in some granitic areas of the world. It also occurs in drainage from some coal mine waste piles and in the effluents from some base metal refinery-smelters.

Other industries that discharge fluorides in process waste streams include coke manufacturers, glass and ceramics producers, transistor manufacturers, electroplating operations, steel and aluminum processors, and pesticide and fertilizer manufacturers.

Glass and plating wastes contain fluoride as HF or F^- ions depending on pH. Fluoride from fertilizer plants is often in the form of SiF_4 as a result of processing phosphate rock. Aluminum producers use fluorides in cryolite Na_3AlF_6 as a catalyst in bauxite reduction. Wet scrubbing of process fumes results in high fluoride levels in effluents with typical levels of 100-150 ppm.

Wastewater from BOLIDEN METALL's Skelleftham works in Sweden contain 124 mg/l F according to BLYTHE, et al. (1981).

Fluoride occurs in a number of mining operations, notably the fluorspar deposits in dolomites of the Marico District in the western Transvaal. Fluoride levels of 4 mg/l and more are commonly found in groundwater in this area. Fluoride levels are generally enriched around fluorspar mining areas in the U.S.A.

At ROOIBERG MINERALS DEVELOPMENT CO., which mines tin in the Transvaal, the available water supply contains 6-12 ppm F^- as described in the Appendix I trip report. Levels of up to 3 mg/l occur naturally in the streams of the area.

ISCOR, a South African steel manufacturer, according to HEYNICKE and VON REICHE (1969), discharged two effluents of 1.0 and 2.5 Mgpd with 2-2.5 and 1.0 mg/l F^-.

In the gold mines of the Evander area of the eastern Witwatersrand, fluoride appears in underground water in concentrations up to 6 mg F/l according to KEMPE (1983). Fluoride also appears in coal mine effluents in the Vereeniging, Transvaal, area. Levels around the acceptable standard of 1.0 mg F/l are common, although isolated occurrences of 3 mg F/l are encountered.

In the U.S.A., municipal water supplies with high fluoride levels occur in several parts of the southwest. According to LETKIEWICZ (1983), there are more than 2,000 water supplies in the U.S.A. in which the fluoride MCL (maximum contaminant level) is exceeded. Of these, nearly all have fluoride levels between the MCL (1.4-2.4 mg/l) and 12 mg/l. There are also known water supplies with F^- levels as high as 30 mg/l but in

these, the concentration of other minerals is usually too high for the water to be used as a potable supply without desalination according to RUBEL (1984).

ENVIRONMENTAL AND HEALTH EFFECTS

Due to the natural affinity of fluoride ions for calcium and phosphates, there is a complex interaction between ingested fluoride and skeletal components. Results of many years of investigation into the health effects of fluoride on animals and humans have not been conclusive. One problem is that skeletal effects, except for dental fluorosis (mottled teeth) in children, develop over long periods of time. There are many documented cases of dairy animals and other animals that have experienced fluoride toxicosis (bone deterioraton due to excessive fluoride) from ingestion of water with fluoride levels from 6-12 mg/l. This affliction results in crippling and death.

Dental fluorosis in children is a direct result of water ingestion with fluoride exceeding MCL by children up to the age of twelve.

Crustaceans accumulate F^- in marine environments. There are believed to have been cases of crustacean accumulation of fluoride near a West German copper refinery due to effluent discharges to the North Sea, but details were not available. This was also a critical issue in licensing of a copper refinery proposed near the coast in South Africa.

REGULATORY LIMITATIONS ON FLUORIDE IN EFFLUENT DISCHARGES

Very few mine-mill permits list fluoride as a restricted contaminant.

	Permit Limit F (mg/l)
Climax - Molybdenum Mine, Climax Colorado, 24-Hour Maximum	3.0
South Africa	
General Standard	1.0
Special Standard	1.0
Drinking Water, Recommended Limit	1.0
Drinking Water, Maximum Allowable	1.5

	FLUORIDE Permit Limit F (mg/l)
Ontario Ministry of the Environment (1978)	
Recommended Maximum - Irrigation	1.0
Water Quality Criteria - Livestock Watering	2.0
Drinking Water, Recommended Maximum	1.2
Drinking Water, Rejection	2.4
U.S.A. Maximum Contaminant Level (MCL)	
12.0°C, 53.7°F	2.4
15.5°C, 60.0°F	2.0
26.6°C, 80.0°F	1.4
Brazil (States of Rio de Janeiro, Sao Paulo, and Minas Gerais)	10.0

TREATMENT FOR FLUORIDE

A variety of treatment methods have and are being used for fluoride removal. A summary of some of these is provided by PATTERSON (1975) in a table which is reproduced here. There are basically two categories of process--precipitation and adsorption.

Summary of Fluoride Treatment Processes and Levels of Treatment Achieved.

Treatment Process	Fluoride Concentration (mg/l) Initial	Final	Current Application	Ref.
Lime Addition	—	10	industrial	4
Lime Addition	1000–3000	20	industrial	1
Lime Addition	1000–3000	7–8 (after 24-hr settling)	industrial	1
Lime Addition	500–1000	20–40	industrial	5
Lime Addition	200–700	6 (16-hr settling)	industrial	6
Lime Addition	45	8	industrial	7
Lime Addition	4–20	5.8 (ave.)	industrial	8
Lime Addition	500	80	industrial	8
Lime + Calcium Chloride	—	12	industrial	9
Lime + Alum	—	1.5	industrial	10
Alum	3.6	0.6–1.5	municipal	11
Alum	80	2	lab scale	9
Hydroxylapatite Beds				
synthetic	12–13	0.5–0.7	municipal	12

14 MAIER (1953)
15 PUBLIC WORKS (1955)

Adsorption methods for fluoride removal are employed for water containing relatively low levels of fluoride, say in the 1-25 mg/l F^- range. The activated Alumina process described below is the most widely used process. Precipitation is used when the fluoride level is so high that the adsorbent would be exhausted too quickly resulting in excessive regeneration reagent requirement or cycles or as a rougher step followed by adsorption for polishing.

PRECIPITATION OF FLUORIDE

As mentioned above, precipitation is used for removal of fluoride from more concentrated streams, say over 50-100 ppm F^-.

Reagents that have been used for fluoride removal include lime, magnesium compounds (e.g., dolomite), and aluminum sulfate (alum).

In addition, at least one attempt has been made to use a combinaton of lime and phosphate to duplicate nature's Ca-fluorapatite.

LIME PRECIPITATION

According to PATTERSON (1975), direct addition of lime is the standard technique for reduction of high concentrations of fluoride ions. Lime reacts with fluoride to produce CaF_2 which has a theoretical minimum solubility of 8 mg/l F at stoichiometric concentrations of calcium (34 mg/l). Reported fluoride removal down to only 10-20 mg/l reflect the slow rate of precipitate formation according to ZABBAN and JEWETT (1967) and SCHINK (1968).

Twenty-four hour contact with lime, however, was reported to reduce fluoride to near the theoretical limit of 8 mg/l (ZABBAN and JEWETT, 1967). At very high lime concentrations, however, improved fluoride removal has been reported, but this may require lime addition of up to 4 g $Ca(OH)_2$ per l of water resulting in an effluent pH of 12 according to ROHRER (1971) and RABOSKY and MILLER (1974). Lime dosing at this level was reported to reduce fluoride from 200 mg/l to 3 mg/l F in 19 hours according to ROHRER (1971).

ZABBAN and HELWICK (1975) reported one case in which total fluoride was reduced to 12 mg/l by lime and $CaCl_2$ addition at pH 7-8.

ROHRER (1971) described an operation where lead and fluoride were precipitated sequentially by addition of trisodium fluoride lime and polyelectrolyte. F^- was reduced to 6 mg/l after 16 hours. Addition of excess lime further reduced the fluoride concentration. Recarbonation provided a way to remove excess Ca^{++} ions and adjust the pH. It is possible that the phosphate addition for lead also helped remove fluoride.

PATTERSON (1975) refers to two experiments in which the addition of sodium hexametaphosphate with alum enhanced fluoride removal (ZABBAN and HELWICK, 1975; MILLER, 1974). In one application of alum plus sodium hexametaphosphate (4:1 ratio), fluoride was dropped from 20 mg/l to below 2 mg/l at pH 7 according to ZABBAN and HELWICK (1975).

Lime addition for fluoride removal employs standard equipment as used in lime softening of municipal water. This includes a rapid mixing basin for chemical addition, a flocculating unit, and a settling basin for solids separation.

According to CILLIE, et al. (1958), the two South African steel mills (ISCOR) with effluent flows of 1 and 2.5 Mgpd were able to reduce fluoride levels to 2-2.5 and 1.0 mg/l F. The fluoride enters the system from electrolytic tinning units and is precipitated with lime prior to the effluent being diluted by combination with total plant effluent.

Normal ways of disposing of the precipitate sludges containing fluoride, according to PATTERSON (1975), is by laggooning, sand bed drying, or filtration.

BOLIDEN-SKELLEFTHAM

BLYTHE, et al. (1981) describe a treatment process for removal of arsenic, heavy metals, and fluoride from a metallurgical plant effluent of BOLIDEN METALL, Skellefthamn, Sweden, in which F is reduced from 124 ppm F at pH 3.5 to 33 ppm at pH 11.5 by lime addition and settling. In order to safely dispose of the gypsum precipitate containing fluoride, the metals and arsenic are first precipitated by sulfide addition at pH 3.8, and the precipitate is recovered by filtration because contamination of the calcium sulfate-fluoride precipitate with metals such as As, Cu, Pb, Zn, etc. would render it unfit for landfill disposal in Sweden.

Nonetheless, the removal of F^- from 124 ppm to 33 ppm also does not indicate a very useful fluoride removal process.

BOLIDEN-Skellefteham: Influent - pH 2.5, 124 ppm F^-
Outflow - pH 11.5, 33 ppm F^-

The BOLIDEN flowsheet and solution compositions at various stages is inserted in Chapter 29 on arsenic removal.

MAGNESIUM PRECIPITATION

PATTERSON (1975) notes that fluoride removal from waters in the lime-soda softening process was observed to be in direct proportion to the amount of magnesium hardness removed, and believed to be due to be due to adsorption of fluoride to the magnesium hydroxide flocs. CULP and SKOLTENBURG (1958) were able to reduce fluoride from 3-4 mg/l to 0.8-1.12 mg/l F. Fluoride reduction is achieved in conjunction with magnesium hardness removal at several municipal water treatment plants in the U.S.A. where fluoride is present at concentrations of 2-3 mg/l, according to SAVINELLI and BLACK (1958).

No plant was found in which $Mg(OH)_2$ or MgO is added specifically for fluoride removal.

ALUMINUM SULFATE (ALUM) PRECIPITATION OF F^-

CULP and SKOLTENBURG (1958) reported that for a water of low hardness containing 3.6 mg/l F^-, simple alum addition plus small quantities of lime for pH control resulted in fluoride reduction to 1 mg/l, but this method was less effective for hard waters.

Addition of alum results in co-precipitation of fluoride onto the aluminum hydroxide. The best removal appears to occur at pH 6-7 with fluoride dropped first from 100 mg/l to 5 mg/l by lime precipitation at pH 11.9 and then to 1.7 mg/l by alum coagulation at pH 5.9-7 according to RABOSKY and MILLER (1974).

ZABBAN and HELWICK (1975) found that fluoride removal from solutions containing up to 100 mg/l F is dependent only on alum dosage and pH with the best performance around pH 7. In one case, at 40 pounds alum per pound fluoride, F^- was reduced to 4.8 mg/l. At alum doses of 200 pounds per pound F^-, effluent levels of 2 mg/l were achieved.

SKRIPACH, et al. (1971) described fluoride and arsenic removal from rare earth processing effluents in which an effluent concentration of 1.5 mg/l F was achieved by adding lime in stages plus superphosphate and alum.

REVERSE OSMOSIS

RUBEL (1984) discusses the use of desalination for fluoride removal. Rejection of fluoride by R.O. is temperature and pH sensitive. At low pH, say 5.5, fluoride rejection is around 50%. At higher pH, CaF_2 precipitation has caused membrane fouling problems. Two possible solutions exist. First is the new seeded slurry reverse osmosis process which effectively avoids membrane fouling problems (when tubular cellulose acetate membranes are used, pH 5.5-6.0 is still the recommended operating range). Secondly, to select one of the new membranes which give a better fluoride rejection at low pH (and it is believed that up to 90% rejection at pH 5.5 has been demonstrated).

Desalting processes are relatively expensive; they cost around $\$0.50/m^3$ recovered water. This is about ten to twenty times the cost of adsorption processes. However, R.O. could nonetheless be useful for fluoride removal if a desalination process has to be used in any case to meet another parameter, e.g., reduction of TDS. If fluoride removal could be achieved, then there would be no extra cost.

ADSORPTION

Adsorption of fluoride from water as it passes through a bed of granular material is routinely practiced and, in fact, is the standard way of removing fluoride from municipal drinking water when the raw supply exceeds allowable limits.

PATTERSON (1975) concludes that adsorption methods are usually only applicable to low-level fluoride waters or for polishing processes after reduction of fluoride levels by previous treatment to the 10-20 mg/l level; otherwise, the need for frequent bed regeneration makes the process economically unfeasible.

Various adsorbents have been used for fluoride removal including hydroxylapatite (synthetic, processed bone and bone char), ion exchange resins, and activated alumina. Of these, activated alumina has now become established as the most reliable and economical process.

HYDROXYLAPATITE

Reduction of fluoride from 12-13 mg/l to 0.5-0.70 mg/l has been reported for a full scale plant by WAMSLEY and JONES (1947). Later reports by SAVINELLI and BLACK (1958) indicated that this unit and others like it were ultimately abandoned due to high chemical costs and bed attrition in which up to 42% of the adsorbent was lost per year. For a similar pilot plant operation in South Africa described by CILLIE, et al. (1958), 10 mg/l

fluoride could be reduced to 1.5 mg/l, but the presence of chlorides in the water reduced filter bed capacity and increased regeneration chemical requirements.

Natural bone char hydroxylapatite can be used but requires phosphoric acid and sodium hydroxide for regeneration which MAIER (1953) found to be too expensive.

ION EXCHANGE

Natural and synthetic zeolite ion exchangers have been examined and reported to be effective for fluoride removal. The exchangers were both pretreated and regenerated with aluminum salts, and it has been established by MAIER (1958 and 1971) that fluoride removal is attributable to aluminum oxide which precipitated in the column bed.

ROHM and HAAS have developed a strong anion exchange resin selective for fluoride, but overall treatment and chemical costs for regeneration were found to be excessive (MAIER, 1953).

ACTIVATED ALUMINA

Activated alumina has been used for many years for fluoride removal from municipal water. A wellknown unit at Bartlett, Texas, has been in successful operation since 1952 using a 500 cubic foot bed regenerated by sodium hydroxide and neutralized with sulfuric acid. Fluoride is reduced from 8 mg/l to 1 mg/l according to PATTERSON (1975) and MAIER (1971). In 1952, the cost of fluoride removal at this plant worked out to \$0.05/1,000 U.S. gal. (\$0.013/m^3). The Bartlett, Texas, plant is no longer in operation according to RUBEL (1984).

Since then, a host of fluoride removal plants have been installed throughout California, Arizona, and Texas. A definitive and comprehensive design manual by RUBEL (1984) has been released by the EPA. Total operating costs for fluoride removal in the U.S.A. today costs between \$0.085 and \$0.20/m^3 (\$0.02-\$0.05/m^3) according to this document which is referenced below.

RUBEL and WOOSLEY (1979) described cost effective operating practices developed at three water treatment plants for removing excess fluoride from drinking water by activated alumina. By the use of these methods, the fluoride removal capacity of alumina was increased by a factor of five. Their paper is also inserted below.

FIGURE 3-2 BASIC FLOW DIAGRAM

FIGURE 6-1 CURVE ILLUSTRATION RULE OF THUMB FOR VOLUME OF WATER TO BE TREATED PER CYCLE VS. RAW WATER FLUORIDE LEVEL

A granular activated alumina is used for fluoride adsorption. The material is a by-product of aluminum production. It is primarily an aluminum oxide which has been activated by exposure to high temperature and caustic soda. The material is highly porous, and the surface area per unit of weight is quite high.

RUBEL (1984) recommends the use of 28-48 mesh Alcoa F-1 grade alumina in defluoridation processes.

CAPACITY OF ACTIVATED ALUMINA FOR F^- REMOVAL

Capacity of activated alumina for F^- removal is very pH dependent as demonstrated by WU (1978) who first suggested that activated alumina capacity for fluoride uptake from water is much greater at pH 5.5 than at 7.0. He reported maximum removals of 4,200 grains/ft^3 at pH 5 with pure NaF solutions. Other investigatiors who have made bench, pilot, or commercial installation studies have reported much lower capacities because they have not understood or chosen to operate at optimum pH conditions.

RUBEL (1984) cites three plants which have operated routinely for years at a low cost meeting the municipal fluoride levels. These are listed below. By paying close attention to pH control, the three plants are able to routinely remove in excess of 2,000 grains/ft^3 (4,600 g/m^3). For higher fluoride concentrations, the activated alumina adsorption capacity increases. For a water with 22 mg/l F^-, the alumina capacity reaches 4,500 grains/ft^3 (10,400 g/m^3).

In this optimum pH range (5.0-6.0), other ions that compete with fluoride for the same adsorption sites are not adsorbed. Included are silica, which is adsorbed in the pH range 6-10, and some hardness ions which are removed in the pH range 7 through 10. Hardness removal occurs at the start of a treatment run. However, activated alumina preferentially adsorbs fluoride; therefore, as the run progresses, hardness removal ceases. At the optimum fluoride removal pH, some organic molecules and some trace heavy metal ions are also adsorbed. However, except for arsenic, these are completely regenerated along with the fluoride. Arsenic presents a problem as it is preferentially adsorbed over fluoride by the alumina at the same optimum pH. Arsenic is more difficult to regenerate than fluoride. Therefore, when excess fluoride and arsenic are present in a water supply, a special treatment technique is required as described by RUBEL and WOOSLEY (1978).

EXAMPLES OF PLANTS USING Al_2O_3 ADSORPTION OF F^-

	Startup Year	U.S. gpm	m^3/d
Lake Tamarisk, Desert Center, California	1970	1,100	6,000
Rincon Water Co., Vail, Arizona	1972	500	2,700
Town of Gila Bend, Arizona	1978	900	4,900
Rooiberg Tin Mine, Transvaal	1985	95	518

CONCEPTUAL DESIGN

Of the many configurations to choose from, i.e, gravity or pressure flow, single or multiple treatment beds, upflow or downflow treatment flow direction, and series or parallel treatment vessel arrangement, RUBEL (1984) reports that the most efficient, cost effective configuration is a parallel downflow multiple bed pressure system. Best cost effectiveness is achieved (for both capital and operating costs) with two treatment beds.

The two-bed series combination yields the highest fluoride loading on the media, and the lowest fluoride level in the treated water, but this is often too low to be desirable. The parallel system allows an opportunity to blend two streams.

REGENERATION OF ALUMINA

Alumina is regenerated using a 1% sodium hydroxide solution. Optimally, 50 percent NaOH solution is used which may require heating as it freezes at 55°F and is very viscous below 70°F. Fluoride ions are repelled from the alumina granules when the pH rises above 10.5.

0.4 gallons (5 lbs.) of 50% NaOH solution is required per ft^3 per regeneration. The caustic requirement for regeneration is a function of the raw water fluoride level which dictates the frequency of regeneration and the volume of water over which the cost must be distributed.

Use of too highly concentrated NaOH solution enhances comsumption of alumina granules.

MEDIA CONSUMPTION

Consumption of alumina should be close to zero in a well-operated activated alumina fluoride water treatment plant. Excessively long backwash periods cause excessive

alumina losses through attrition and elutriation. Monitoring of backwash fluids can help detect this.

During regeneration, excessively high and/or low pH exposure attacks the media. If the regeneration solution exceeds 1.5% NaOH, the solution is aggressive to activated alumina.

Also, if the pH of the post regeneration neutralizing solution (acid addition) is below pH 2.0, the alumina dissolves very rapidly with resulting losses.

Finally, alumina can be lost through the effluent underdrain collection system within the bed. If alumina grains ever appear in the treated effluent, this indicates that the collection system is in need of repair.

A conservative bed replacement estimate according to RUBEL (1984) is ten percent per year.

OPERATING SEQUENCE

1. Feed pH adjustment to Ph 5.0-6.0.
2. Adsorption mode - downflow.
3. Backwash mode.
4. Regeneration.
5. Neutralization after regeneration.

Raw water is used in each of these steps.

Details of the operation of an activated alumina plant for defluoridation are provided by RUBEL (1984) including several knowhow items which would prove helpful in optimizing results for a given plant.

Fines that accumulate on top of the alumina bed should be removed to avoid an unnecessarily high pressure drop across the bed when commencing a run.

BACKWASHING

Backwashing of the bed with raw water after each run prior to regeneration is important to remove suspended solids filtered from the feedwater. Upflow backwash expands the bed. Backwash at 8-9 gpm/ft^3 expands the bed about 50%, which is recommended. Normally, backwashing lasts ten minutes. RUBEL (1984) provides a valve operation chart for the backflush mode.

REGENERATION

Regeneration of the bed on completion of an adsorption run generally includes two discrete regeneration steps. First is upflow regeneration following draining of the bed after backflushing. Regeneration is followed by an upflow rinse. The unit is then drained to the top of the bed prior to the second regeneration step which is downflow. Both steps use 1% (by weight) NaOH solution.

A skilled operator can reduce the concentration of NaOH to 0.75% and achieve the same high regeneration efficiency; however, below 0.75%, the efficiency drops rapidly. At this lower caustic concentration, the saving in NaOH consumption amounts to 20%.

As a rule of thumb, fifteen gallons of 1% NaOH solution is needed per cubic foot of treatment media. The minimum time for the regenerant solution to flow through the bed is thirty minutes. Thirty-five minutes is recommended for a 5' bed. A flow of 2.5 gpm/ft^2 for thirty-five minutes per regeneration is usually sufficient, which equates to 0.2 gallons of 50% NaOH per cubic foot of treatment media for each regeneration step (upflow and downflow).

After backflush, prior to upflow regeneration, the bed must be drained to remove water which dilutes the caustic concentration. Upon completion of draining, the upflow regeneration starts. On completion of the upflow regeneration, the caustic feed pump is turned off and the day tank refilled. Raw water continues to flow for sixty minutes at 2.5 gpm/ft^2 upward through the bed to flush out the fluoride. After this rinse step is completed, the vessel is drained to the top of the treatment bed, again to remove dilution water. Then, downflow regeneration is followed by a draining period prior to the start of the neutralization mode.

NEUTRALIZATION

Neutralization is critical to the success of the following adsorption (treatment) run. The objective of this mode is to return the bed to the treatment mode as rapidly as possible without dissolving the activated alumina. The pH of the alumina upon completion of regeneration is 12 plus. It must be adjusted down to 5.5. Therefore, it must pass through pH ranges where ions that compete for adsorption sites on the alumina will be loaded into the bed. The minimum pH that can safely be reached is pH 2.5. A lower pH is too aggressive and is not recommended.

After 15 minutes of downflow regeneration, the flow is adjusted to the normal treatment mode rate. The acid pump is started, and the pH of the raw water adjusted to 2.5. Acid feed rate again varies with the alkalinity of the raw water. The raw water flow rate may have to be reduced to achieve pH 2.5 at the maximum acid pump feed rate.

As the neutralization mode proceeds, pH of the treated water gradually drops below 12. The rate of pH reduction increases at an increasing rate. As the treated water drops below ten, the treated water fluoride level begins to drop below that of the raw water. At that time, treatment begins. At the point where the fluoride level drops below the MCL, the water becomes usable and can be directed to storage even if the pH is still high (say pH 9.5).

When the treated water pH drops to 8.5, the raw water pH is adjusted up to 4.0 as the bed rapidly neutralizes. When the treated water drops to pH 6.5, the raw water is adjusted up to pH 5.5 where it remains through the duration of the run.

Volume of wastewater produced during the regeneration of the alumina bed varies with the physical and chemical characteristics of the raw water. A useful rule of thumb is 300 U.S. gallons per ft^3 of media, i.e., 40 m^3 wastewater per m^3 media per regeneration.

Typical volumes of wastewater generated during each regeneration cycle for a hypothetical plant as described by RUBEL (1984) are:

Backwash	60 U.S. Gal.
Upflow Regeneration	15 U.S. Gal.
Upflow Rinse	30 U.S. Gal.
Downflow Regeneration	15 U.S. Gal.
Neutralization	180 U.S. Gal.
TOTAL	300 U.S. Gal.

Operating experience for each given plant will soon come up with deviations from these quantities.

DISPOSING OF WASTEWATER

All the known fluoride treatment plants using activated alumina are located in areas with net evaporation climates and, as such, are suitable for disposal of the regeneration wastewater containing flouride into lined evaporation ponds.

LABORATORY REQUIREMENTS

RUBEL (1984) recommends that the operator of an activated alumina fluoride removal plant be equipped with the operations and maintenance (O&M) manual for the plant and also the latest edition of Standard Methods for the Examination of Water and Wastewater by AWWA-APHA and basic laboratory equipment. Primary analytical needs are to determine pH and fluoride. Fluoride measurement can be by ion-specific electrodes provided the

:t buffer (TISAB) is employed for the water to be treated. There are also two te wet chemistry methods using SPADNS and Alizarin. Distillation and/or correction terferring ions (e.g., alkalinity, aluminum, iron, sulfate, etc.) are required for te results.

,TING COSTS FOR DEFLUORIDATION BY ACTIVATED ALUMINA

include the following:

- Treatment chemicals.
- Operator labor costs.
- Utility costs.
- Replacement alumina.
- Replacement parts and miscellaneous materials.

L (1984) discusses each cost item in some detail.

ding to RUBEL (1984), the U.S. price for ALCOA F-1 28-48 mesh activated alumina s from $0.697/lb to $0.516/lb depending on quantity.

ıting costs (1984) vary as follows:

Operating Cost Items		U.S. Dollars per 1,000 U.S. Gallons Treated Min. $	Max. $	Ave.
Treatment Chemical -	Acid	0.02	0.08	0.05
	Caustic	0.02	0.12	0.05

CAPITAL COST FOR ACTIVATED ALUMINA DEFLUORIDATION PLANT

RUBEL (1984) estimated costs for a 600 U.S. gpm (3300 m³/d) defluoridation plant in a warm Arizona climate at $347,000 of which $138,000 was for the lined wastewater evaporation pond. The cost breakdown was as follows:

Flowrate: 600 U.S. gpm, 3300 m³/d.

Process Equipment	
Treatment Vessels	$ 33,000
Treatment Media - Alumina	20,500
Process Piping, Valves, and Accessories	16,400
Instruments and Controls	8,300
Chemical Storage Tanks	21,000
Chemical Pumps, Piping and Accessories	6,300
Subtotal	$105,000
Process Equipment Installation	
Mechanical	$ 36,000
Electrical	7,000
Painting and Miscellaneous	4,500
Subtotal	$ 47,500
Miscellaneous Installed Items	
Wastewater Evaporation Pond - Lined	$138,000
Building and Concrete	28,000
Sitework, Fence, and Miscellaneous	11,000
Subtotal	$177,000
Contingency 4%	17,000
TOTAL	$347,000

The Removal of Excess Fluoride From Drinking Water by Activated Alumina

Frederick Rubel Jr. and R. Dale Woosley

Described here are cost-effective operating practices developed at three water treatment plants for removing excess fluoride from drinking water by activated alumina. By use of these methods the fluoride removal capacity of alumina was increased by a factor of five.

Under the national Interim Primary Drinking Water Regulations maximum contaminant levels (MCL) in potable water supplies have been established for ten inorganic chemicals, including fluoride. The MCL for fluoride varies from 1.4 to 2.4 mg/L depending upon the annual average of the maximum daily air temperatures (Table 1). If the prescribed maximum level is to be enforced, its achievement must be technically and economically feasible.

Since it became known that excess fluoride in drinking water caused mottled teeth in children,[1] many methods of removing fluoride have been developed. One of them employs activated alumina to defluoridate water supplies. Although many investigators have found that activated alumina is quite effective in reducing fluoride to very low levels in treated water, there is an abundance of confusion as to the useful capacity of activated alumina.

Churchill,[2] in his 1936 patent on the use of activated alumina for fluoride removal, states that a pH of 5 to 6.5 should be used during treatment for best results. There is no stated capacity in his patent. E.A. Savinelli and A.R. Black,[3] in their 1958 bench experiments, showed that a capacity of 7800 g/m³ (3400 grains/cu ft) was achieved when treated water pH was 5.6. Their studies were made with tap water to which sodium fluoride had been added. Yeun C. Wu,[4] in a recent article, again shows that treatment pH is quite important for high removal capacities. He reports maximum removals of 9600 g/m³ (4200 grains/cu ft) with treatment at pH 5.6 in pure sodium fluoride solutions. Other investigators[5-9] who have made bench, pilot, or commercial installation studies report much lower capacities because they have not understood or chosen to operate at optimum pH conditions.

Two plants that have had several years of low-cost experience in producing waters with fluoride concentrations reduced to acceptable levels are the Lake Tamarisk plant at Desert Center, Calif., with nine years of operation, and the Rincon Water Co. plant at Vail, Ariz., with six years of operation. A third plant began operation in Gila Bend, Ariz., in May 1978. By paying close attention to pH control, the three plants are able to operate routinely with removal capacities exceeding 4600 g/m³ (2000 grains/cu ft). Removal capacities exceeding 7000 g/m³ (3200 grains/cu ft) were observed during the pilot work done at Gila Bend, Ariz., to confirm that the developed operating practices would work on that water supply.

Development work with pilot-plant equipment on a continuing basis has perfected the water treatment and alumina regeneration processes at each of these locations. This article outlines the operating practices developed for removing fluoride to acceptable levels.

Fluoride Removal Technology

This article is based on pilot-plant experiments and plant data for which granular activated alumina[a] (mesh size 28 to 48) was used.

The basic principles of fluoride removal technology are

1. Optimizing the environment for sorbing of fluoride ions to activated alumina surfaces
2. Preventing competing ions from occupying alumina surfaces that should be reserved for fluoride ions
3. Upon regeneration of an expended treatment bed, taking all steps necessary to remove all fluoride ions from the bed before returning it to treatment.

There are also many "common sense" principles that apply to the process which, though important, are not as critical as the three listed.

There are four modes of operation: treatment, backwash, regeneration, and neutralization. Operating details for each mode are discussed here.

Treatment mode for virgin or regenerated treatment bed. The optimum environment for fluoride removal exists when raw water pH is adjusted to 5.0–6.0 by sulfuric acid injection. Because acid feed rates are a function of the raw water alkalinity, they vary from one water to another. The best results obtained to date have occurred when the raw water pH has been held carefully at 5.5. In this environment the attraction of the fluoride ion to the activated alumina surface is most favorable and interference by competing ions is minimal. Adsorption is the most probable mechanism for fluoride ion removal from water, but because work in this area is still in progress, discussion of mechanism is premature. In applications

Fig. 1. Typical Operational Run at Gila Bend, Ariz.

to date, treatment bed capacities consistently have exceeded 4600 g/m³ (2000 grains/cu ft), and some runs have exceeded 9200 g/m³ (4000 grains/cu ft).

As raw water pH moves above 6.0 or below 5.0, fluoride removal capacity deteriorates at an increasing rate. For example, from previous experiments it has been shown that at pH 7.0 bed capacity is about 1100 g/m³ (500 grains/cu ft). Though efficiency might appear to be the same, breakthrough occurs earlier and treatment runs are shorter. Fluoride removal efficiency at optimal pH approaches 100 percent, as indicated by treated water fluoride concentration well below 0.1 mg/L during portions of the treatment run at each installation. This efficiency is achieved in waters with different chemistries including varying fluoride levels (Table 2). Superficial residence time (flow time through the bed neglecting the volume of bed material) is also a limiting factor: a 5-min minimum is a practical limit for maximum removal efficiency. Best results occur with flow directed down through the bed. Care must be taken to prevent a wall effect or channeling.

The initial effluent pH is high, with no fluoride removal, as explained in the discussion on neutralization mode. After a short period both pH level and residual fluoride drop to acceptable levels. At that point usable water can be directed to storage or distribution. Fluoride level drops rapidly to a very low level and remains there until breakthrough begins, at which point it increases gradually until the treatment run is terminated.

Treated water pH drops below 6. Because water of this pH is corrosive, the treated water pH must be adjusted to a desirable level (about 7.5) by injection of sodium hydroxide or by blending.

Backwash mode. For two reasons it is important that the bed be backwashed with raw water before each regeneration: first, any suspended solids that have been filtered from the raw water by the treatment bed tend to blind the bed and must be removed; second, even though filtration may not have taken place, the downward flow tends to pack the bed. Therefore, an upflow backwash expands the bed, breaking up any tendency toward wall effects or channeling. A backwash rate of 5–6 mm/s will expand the bed about 50 percent, which is adequate. Care must be taken to avoid backwashing granular bed material out of the treatment unit. Normally, backwash is completed within 10 min.

Regeneration mode. The object of regeneration is the removal of all fluoride ions from the bed before any part of the bed is returned to the treatment mode. The most successful regeneration is accomplished in two steps: the first is upflow immediately after backwash while the bed is still expanded, followed by an upflow rinse. The unit is then drained to the top of the treatment bed. The second regeneration step is downflow immediately followed by the neutralization mode. Regeneration steps employ 1 percent (by weight) sodium hydroxide solution flowing at a rate of 1.7 mm/s. With a standard treatment bed depth of 1.5 m, each regeneration step takes 35 min. Chemical consumption in each regeneration step is 27 L of 50 percent NaOH per cubic metre of treatment media (0.2 gal/cu ft). The intermediate upflow rinse flows at a rate of 3.4 mm/s for a period of 30 min. If the treatment bed depth varies from standard, flow rates and times must be adjusted. The regenerant solution is usually an in-line dilution of 50 percent sodium hydroxide with raw water, with the sodium hydroxide maintained at or above 21° C to prevent freezing.

Neutralization mode. The object of this step is to return the bed to the treatment mode as rapidly as possible without dissolving the treatment media. As soon as the second (downflow) regeneration step has been completed, all of the fluoride should have been removed from the bed. At this point the bed is drained again to the top of the treatment media. Raw water with pH adjusted to 2.5 is then fed downflow at the normal treatment flow rate (Fig. 1). Sulfuric acid concentrations again vary with the alkalinity of the specific raw water. The entire bed has a pH range from 12.5 to 13.0, and as the top of the bed begins to

* This is ambiguous: 27 or (2x27 = 54L) ?

neutralize and enter a treatment mode, the fluoride level in the treated water starts to drop below that of the raw water. Treated water pH also begins to drop. As the fluoride level drops below the mandatory limit, the water becomes usable and can be directed to storage or distribution. pH may still be high (9.0–9.5) in the treated water; however, this water can be blended with treated water of lower pH from other treatment units. When the pH is 9.0 to 9.5, the raw water pH is adjusted to 4.0 as the bed rapidly neutralizes. When the treated water pH drops to 7.5, the raw water pH is adjusted to 5.5, where it is maintained throughout the remainder of the run.

Initial Start-Up Procedures

When the bed material is first placed into the treatment unit, the vessel should be half filled with water. As the activated alumina is poured into the bed from above, the water dissipates the heat generated by the heat of wetting of the activated alumina, thereby preventing cementing of the bed. The water also aids in separating fines from the granular material; protects the underdrain assembly from impact; and initiates stratification of bed material. Once the bed is in place, it must be backwashed for an extended period until all of the alumina fines are flushed from the virgin bed. The flow is then reversed and downflow treatment begins for the virgin run.

Blending of Treated Water

Blending can take place in either large reservoirs or the treated water main. During a treatment run there is a long period when the fluoride level of the treated water is well below desired levels. As breakthrough occurs there is a long period of slowly increasing fluoride concentration in the treated water. It has been found that treated water can continue to flow to storage or distribution until the fluoride concentration reaches one and one half to two times the maximum allowable level; the resulting total average fluoride level continues to meet the prescribed fluoride level (one half the maximum allowable level).

When there is a large reservoir in which the major portion of a treatment run can be stored, blending takes place there. At locations where the reservoir is not large and there are two or more treatment units, staggered regenerations accomplish the same result; that is, a regenerated treatment unit will produce water of very low fluoride content while a second unit in the later stages of its treatment run may be producing water of a higher fluoride level. By mixing the effluent from the two units in the treated water main, an average fluoride concentration near the prescribed level can be maintained. Similarly, the treated water of high pH occurring early in the run for one unit can be blended with the low pH effluent of another unit in a later stage. The benefit of this blending is short-lived; soon the pH of the blended streams requires adjustment.

Disposal of Wastewater

The wastewaters resulting from backwash, regeneration, and the early part of neutralization are not suitable for consumption and must be discarded. The backwash water, which is only raw water, can be discharged to existing storm water disposal systems. The only objectionable feature of the regeneration waste is the high concentration of fluoride ions that cannot be returned to the groundwater aquifer. Its high pH can be neutralized. Disposal of waste of high fluoride concentration must comply with local wastewater discharge standards, which vary. Existing plants concentrate the waste in lined evaporation ponds; eventually the concentrated waste must be transferred to an acceptable disposal site or the fluoride must be reclaimed.

The volume of wastewater is approximately 4 percent of the total throughput.

Materials of Construction

The cost of a treatment plant is a function of the quality of the construction materials in its design. Trouble-free, low-cost plant operation can be achieved only by proper selection of materials to meet the service requirements of the process. Without considering the materials for concentrated acid and caustic

Treatment Units at Gila Bend, Ariz.

Treatment Plant at Gila Bend, Ariz.

Lake Tamarisk Treatment Plant at Desert Center, Calif

Rincon Treatment Unit Acid Line in Foreground

systems, treatment system materials must be suitable for service under the following conditions: (1) potable water system; (2) ambient temperatures (provision for thermal expansion); (3) exposure to sunlight (or protected); (4) pH 2-13; and (5) ease of maintenance (remove and replace with minimum logistics). Materials for the chemical storage and handling systems should comply with chemical manufacturers' guidelines.

Operator Requirements

A qualified operator for a fluoride removal water treatment plant requires thorough fluoride removal process training, preferably at an existing treatment plant. The operator must be able to service pumps, piping systems, instrumentation, and electrical accessories. The operator must be totally informed about the characteristics of sulfuric acid in all concentrations and sodium hydroxide in all concentrations. Safety requirements as to clothing, equipment, and antidotes must be thoroughly understood and executed. The operator must be trained to run routine water analyses including at least two methods for determining fluoride levels. He needs simple mathematics for record keeping during a treatment run and for operation cost accounting. Above all, the operator must be dependable and conscientious.

Cost of Operation

The cost of operating an alumina fluoride removal system including chemicals, electricity, bed replacement, replacement parts, and labor, currently falls in the range of 2-5¢/kL (8-20¢/1000 gal) of treated water. Individual plant operating costs vary as functions of raw water fluoride level, plant capacity, treated water consumption, electric utili-

ty rate, labor costs, delivered chemical costs, and so forth. The low operating costs at the three operational plants discussed in this article are shown in Table 3. The 1977-78 materials and construction costs for the plant at Gila Bend were less than $200 000. The plant was designed for 2.8×10^{3} m³/day (0.75-mgd) average production with peak capacity of 4.8×10^{3} m³/day (1.3 mgd).

Conclusion

Low operating costs for removing fluoride from potable water can be achieved with an activated alumina system. Reliability of plant equipment, materials, and operational costs have been documented through nine years of commercial field experience. Installation and operating costs are compatible with limited public budgets and funding programs. All materials and equipment are available, and there is existing technology to assist in designing a plant to meet fluoride MCLs.

EXPERTISE AND ENGINEERING

Unquestionably, the world expert on flouride removal is:

RUBEL AND HAGER, INC.
4400 East Broadway
Tuscon, AZ 85711
(602) 327-6616
Frederick Rubel, Jr., P.E.

His excellent design manual "Removal of Fluoride from Drinking Water Supplies by Activated Alumina," EPA Report No. EPA-600/2-84-134 of August, 1984, is available from:

NATIONAL TECHNICAL INFORMATION SERVICE
Springfield, Virginia, U.S.A.

ROOIBERG MINERALS DEVELOPMENT CO. LTD.

In 1984, two water defluoridation plants, each of 518 m^3/d, were installed to treat minewater containing 6-10 mg/l F as described in Appendix I.

In this case, the original testwork was carried out by the National Institute for Water Research. Final design and construction was by:

PRENTEC (PTY) LTD.
Post Office Box 1433
Edenvale 1610

609-5216
John A. Buchanan

Capital investment for the two plants including the reticulation system was R0.75 million. Operating costs are estimated at U.S. \$0.20/m^3 U.S. \$0.76/1000 U.S. gallons which is relatively high even taking into account that these are smaller plants with higher relative overhead, and the cost includes engineering and taxes.

In this case, the regeneration wastewater is used to pump tailings to the tailings dams.

INTRODUCTION

Iron occurs in solution as ferrous and/or ferric ions depending on pH and dissolved oxygen concentration. At neutral pH and in the presence of oxygen, soluble ferrous iron (Fe^{2+}) is rapidly oxidized to ferric iron (Fe^{3+}) which readily hydrolyzes to form the insoluble precipitate ferric hydroxide $Fe(OH)_3$.

Below pH 6, the rate of ferrous iron oxidation to ferric is extremely slow. Therefore, acid and/or anaerobic conditions are necessary for iron to exist in solution.

In addition, at pH values above 12, ferric hydroxide will redissolve due to the formation of the $[Fe(OH)_4]^-$ complex anion. Also, even in acidic, anaerobic conditions, if a source of sulfide ions is present, iron will be removed from solution as FeS or Fe_2S_3. Ferric and ferrous ions are also solubilized in the presence of cyanide due to the formation of ferri- and ferrocyanide complexes. Such complexes present considerable difficulties for both iron and cyanide removal. Since the sulfide precipitates are more stable than the cyanide complexes, however, addition of sulfide to polish solutions may offer one possible way to remove iron and to render any cyanide ions amenable to oxidation if necessary.

Ferrous ions and ferrous hydroxide are greenish in color. Ferric ions in solution are yellow, but when ferric hydroxide precipitates, the precipitate is red-brown and gelatinous. Acid mine drainage in contact with air turns red brown in color because of the suspension of colloidal ferric hydroxide particles.

Acid mine drainage, which includes water draining or pumped from both underground and open pit mines, seepage and runoff from mine wasterock, tailings ponds, and surface runoff from any area affected by mining (e.g., concentrate stockpile areas, mine-mill-smelter yards, roadbeds, and rail beds constructed with wasterock, etc.), usually contains iron often with minor amounts of other metals, e.g., Cu, Zn, Ni, and Mn.

Iron in acid mine drainage often helps in the removal of other metals because it acts as excellent co-precipitant. However, ferric hydroxide is a gelatinous, difficult to settle precipitate usually with a very low terminal solids density which requires large lagoons for disposal unless special measures are adopted.

OCCURRENCE OF IRON

Surprisingly, iron contamination of water occurs prolifically around mines other than iron mines. Acid mine drainage is one of the most formidable challenges facing the mining industry. It affects base metal mines, especially massive sulfide deposits, uranium mines particularly of the Elliot Lake and Witwatersrand type, gold and silver mines associated with sulfides and, of course, the enormous coal mining industry. It is the ubiquitous occurrence of iron sulfide minerals, e.g., pyrite, pyrrhotite, and marcasite, that generates acid mine drainage on oxidation.

Acid mine drainage inhibition and treatment has been discussed in separate chapters, and most of that discussion would be applicable to this discussion on iron removal.

Iron sulfide minerals may comprise only 1-3% of a mine tailing, or they may be as much as 95% of a tailing material. Both generate acid mine drainage.

In waters of low dissolved oxygen, iron may be reduced to the ferrous form, and some iron may be in solution as the ion. Ferrous iron may be released from lake sediments if the water above the sediments becomes totally anaerobic; the release of iron is the result of a shift in the redox potential below a critical level at the sediment surface according to ONTARIO MOE (1974).

ENVIRONMENTAL IMPACT OF IRON

Iron is an essential mineral constituent for just about all life forms.

In the public water supply, soluble iron at levels in excess of 0.3 mg/l Fe can cause staining of tile surfaces.

Excessive levels of iron in drinking water (around 0.5 ppm and more) start to impart a flavor to water, and 1.0 mg/l Fe is cause for rejection as drinking water.

Iron in receiving waters (lakes and streams) interferes with aquatic biota. It is the fouling properties of iron hydroxide that apparently does more damage than soluble iron in water. There are several types of impact:

1. Impairment of fish larvae respiration.
2. Impairment of gill action through fouling.
3. Impairment of streambed habitats by formation of ferricrete.
4. Fouling of streambed plants and algae.

It is concluded that iron released into the aquatic environment will almost always be precipitated. Fine flocs formed at low iron concentrations may sometimes do more damage than large flocs formed at higher iron concentrations.

The criteria for total iron levels in freshwater at which the environment is protected is 300 ug/l total iron in Canada, and 1,000 ug/l total iron in the U.S.A. U.S. EPA (1972), CANADA (1979).

In the marine environment, a criteria level of 300 ug/l has been set by U.S. EPA (1972). ONTARIO MOE (1979) provides a lengthy discussion on the effects of iron on several aquatic algae and organisms which was found to be highly variable. Below 300 ug/l Fe, it was concluded, all aquatic species would be protected since below this level iron flocs would be unlikely to form.

Another environmental effect of iron in solution is the pH reduction that occurs during the hydrolysis of ferrous to ferric iron.

REGULATORY LIMITS FOR IRON

In reviewing the permits for discharge of effluents encountered during the course of this investigation, it was found that iron is not very often included. The only cases found which limit iron levels in their discharge are as follows:

	Iron Total Limit (mg/l)
Mount Emmons, Colorado NPDES	1.0
NORANDA Grey Eagle Zero Discharge Except Excess Water Can Be "Irrigated" After Treatment	0.20
Climax Molybdenum, Climax, Colorado	0.60
Typical Arizona Copper Concentration	
25-Hour Max.	1.00
30-Day Ave., Max.	0.50
Public Water Supply, U.S. EPA (1976)	0.30
Public Water Supply, Canada (1979)	0.05
South African Drinking Water SABS (1971)	
Recommended Maximum	0.10
Rejection Limit	1.00

TREATMENT FOR IRON

The most usual treatment process for iron is oxidation to ferric and precipitation of ferric hydroxide near pH 7 where the solubility of iron is at a minimum. Often, when other metal ion contaminants must be removed as well, a somewhat higher pH is employed.

Fe (ug/L) IRON

Summary of North American Water Quality Criteria for Iron

FIGURE 14.—Fields of stability for solid and dissolved forms of iron as function of Eh and pH at 25°C and 1 atmosphere of pressure. Activity of sulfur species 96 mg/l as SO_4^{-2}, carbon dioxide species 1,800 mg/l as HCO_3^-, and dissolved iron 0.0086 mg/l.

At pH 7.0-7.5 and above, conversion of ferrous to ferric iron occurs very rapidly as described in the section on acid mine drainage treatment. Spontaneous formation of ferric hydroxide then results in iron removal by precipitation.

JOBIN and SHOSH (1972) found that the rate of ferrous oxidation is dependent on pH, buffer intensity in bicarbonate systems, and upon the concentration of organic matter. Organic compounds containing hydroxyl and carboxyl functional groups seem to greatly reduce oxidation rates and can result in high soluble iron levels if the organic substances do not readily break down.

If iron is present in acid waters as the ferric ion, simply neutralizing the acid will precipitate the iron.

In some cases where there is a significant quantity of dissolved CO_2 in the water, this will be present as bicarbonate HCO_3^- in the acidic water. The bicarbonate/carbonate system buffers the water and consumes more lime than would otherwise be required to increase the pH over 7. By vigorous aeration of the water to remove CO_2 from solution, it is possible to reduce the amount of lime needed to modify the pH and precipitate iron. This process is applied at BETHLEHEM STEEL CORP.'s Panther Valley Division anthracite coal mine water treatment plant.

Iron removal from municipal water supplies has been practiced for many years. Iron levels in ground water supplies are characteristically 1-10 mg/l as ferrous iron. Ground waters are typically anoxic and weakly acid, usually high in CO_2. Aeration to remove CO_2 (and consequently increase pH) and to oxidize ferrous to ferric comprises the standard municipal water treatment. Lime is frequently employed for additional pH adjustment. The following table summarizes the treatment performance for some municipal iron treatment plants as reported by PATTERSON (1975).

SUMMARY OF MUNICIPAL PLANT PERFORMANCE FOR IRON

Process	Iron Concentration mg/l		
	Influent	Effluent	Reference
1. Chlorination, Alum-Lime-Sodium Silicate Precipitation and Sand Filtration	1.5	0.05	HANEY (1964)
2. Aeration, Lime, Sand Filtration	2.4	0.0	HANEY (1964)
3. Aeration, Sand Filtration	2.5	0.13	GARDNER and STIKA (1964)
4. Aeration, Coke Bed Filtration, Sedimentation, Sand Filtration	5.7	0.13	McCRACKEN (1961)
5. Lime, Aeration, Diatomite Filtration	10	1.10	KOLLIN (1962)

In the treatment of acid mine drainage, it is usually necessary to neutralize relatively high concentrations of acid and to precipitate considerably higher concentrations of iron;

this consumes much more lime and generates much larger volumes of precipitate sludges which must be disposed of.

TREATMENT OF IRON IN ACID MINE DRAINAGE

Treatment Chemical	pH	Initial Iron (mg/l)	Effluent Iron (mg/l)	Reference
Limestone Slurry		145	5	PATTERSON (1975)
Lime		157	1.6	PATTERSON (1975)
Soda Ash		126	2.3	PATTERSON (1975)

During the course of this investigation, the following iron removal results were idendified:

Operation	Reagent	Treatment pH	Iron in Influent (mg/l)	Iron in Effluent (mg/l)	Plant Capacity
AMAX, Mount Emmons	Lime, F_L, F	10.6	27-800	0.05-0.30	11,000 m^3/d
Brunswick Mining	Lime, D	9.03	951	2.35	
ERPM - Rand Mines	HDS	7.3	650	Nil	50,000 m^3/d
ERPM - Rand Mines	R.O. Pilot	4.5	6.0	0.06	5 m^3/d
Falconbridge, Onaping	Limestone, D	7.0	2-4	0.04-0.60	-
Gilman, Colorado	Lime, D	9.60	50-180	0.10-1.20	500-700 m^3/d
INCO, Copper Cliff	Lime, S	10.0	13.4	0.35	272,000 m^3/d

TREATMENT COSTS

Operation	Plant Size	Cost/m³	Capital
INCO Copper Cliff	272,000 m³/d	US $0.06/m³	C $4.1 Million (1975)
Eastern Canada Mine #6	2,900 m³/d	US $0.60/m³	
Falconbridge, Sudbury	16,000 m³/d	US $0.01/m³ (1979)	C $257,000 (1978)
R. Osmosis	Conceptual	US $0.50/m³	

DISCUSSION

1. The HDS process described in Appendix I in trip reports for:

   RAND MINES, ERPM
   KROMDRAAI COAL MINE
   NORANDA, GECO
   NORANDA, WAITE-AMULET

   The HDS process offers a significant advantage in the treatment of acid mine drainage containing high levels of iron in that a dense, stable sludge can be produced which is compact and safe to dispose of and non-amphoteric.

2. In the section on acid mine drainage, HDS application at several additional operations is discussed in which sludges with up to 50% solids are generated.

3. BETHLEHEM INTERNATIONAL ENGINEERING CORP., Bethlehem, Pennsylvania, has shown that HDS sludge from acid mine drainage yields a stable waste material when mixed with a pozzolan that is suitable for landfill disposal.

4. The Wannamaker Continuous Concentrator has been demonstrated for acid mine drainage treatment from the Argo tunnel. This is a form of cross-flow micro-filtration technology using sludge recycle which also achieves a relatively low iron value in the treated effluent and a precipitate with a higher percent of solids.

5. The USBM at Pittsburgh has shown the effect of a natural bog in raising the pH of acid mine drainage and precipitating iron as ferric hydroxide.

6. BARRET, HAENTJENS AND CO. of Hazelton, Pennsylvania, has developed a new jet pump which effectively flash-precipitates iron from acid mine drainage at a lower pH. This device is described in the section on AMD treatment.

7. Although various processes will be needed to polish effluents from mining and milling operations, the magnitude of the acid mine drainage problem is so great that attention will have to focus on prevention of the problem rather than treatment technology.

8. It was pointed out above that neutralization of acid mine drainage to a pH in excess of 7.0 at which ferrous ions oxidize rapidly to ferric ions can be quite expensive. An interesting innovation in this respect was proposed and described by MIHOK (1969) who found in laboratory batch flow tests conducted with high iron acid mine drainage treated with activated carbon that the iron was rapidly catalytically oxidized by the activated carbon. The ferrous iron content of an acid mine water flowing through an aspirated activated carbon column was reduced from around 700 to 10 ppm in less than one minute at pH around 2.5.

   The activated carbon was used repeatedly with little loss in efficiency and no discoloration or solids deposition. In the batch tests, about one-third of the iron was adsorbed by the carbon, but with continuous flow, little iron adsorption is expected. (No reasons were given.)

   It was proposed that a catalytic oxidation step in the treatment of acid mine waters containing ferrous iron would facilitate neutralization providing precise control of pH, lower reagent costs, and elimination of aeration equipment. Also, limestone might possibly then be suitable for acid mine drainage neutralization which would result in further cost savings compared with lime, provided ferruginous coatings that passify limestone can ve avoided.

   Although this revelation was made in 1969, no commercial application has been identified. No reasons for this were identified. In the original tests, a commercial type coal-base activated carbon 12 x 40 mesh was used.

9. At Jabiluka Uranium, LEVINS (1979) reported levels of 2,000-5,000 mg/l Fe in acidic uranium ore leach tailings/raffinate waste at the Alligator Rivers region of Northern Territory, Australia. After adjustment to pH 8, the iron level dropped to 1 ppm. Several other contaminants are precipitated when lime is added to pH 8, including Al, Ba, Cr, Cu, Mg, Mn, Pb, U, V, Zn, P, Si, and SO_4, which all would accumulate in the precipitate sludge.

10. <u>Biological Oxidation of Ferrous Iron Aids Precipitation</u>: WICHLACZ (1985) described the kinetics of ferrous iron Fe(II) oxidation by attached bacteria in bench-scale

rotating biological contactors (RBC). Oxidation efficiencies of better than 80% were obtained over the range of Fe(II) mass loadings tested (0.14-2.34 mg Fe(II)/ cm^2/hr.). The amount of oxidation and the rate depended on a combination of influent and bulk fluid Fe(II) concentration as well as flow rate. A model describing attached bacterial growth and oxidation rate as a saturation function of substrate utilization was developed and tested. The maximum oxidation rate constant was proportional to flow rate, and the substrate concentration in the reactor varied with influent substrate concentration. The model allowed prediction of metabolic constants and included terms for both constant and growth rate dependent maintenance energies.

Toward the end of Chapter 25 on "Removal of Contaminants," reference is made to additional testwork in which rotating biological contactors have been used to oxidize ferrous to ferric.

Idaho Falls, ID

11. Dissolved Air Flotation: An expensive aspect of neutralization and precipitation plants is the removal of the iron hydroxide precipitate. Clarification plants are sized for the hydraulic flow rate pretty much regardless of the precipitate loading being removed from suspension. BOSMAN (1983) of the ANGLO AMERICAN RESEARCH LABORATORIES pointed out that for low precipitate loadings, dissolved air flotation can offer a much more compact clarification step. Since the volume of precipitate in such cases is small in any case, solids density of the floated concentrate is pretty much irrelevent.

    This aspect is also discussed in chapters 12 and 24 on removal of suspended solids and acid mine drainage treatment.

12. Reverse osmosis using the seeded slurry innovation has been successfully demonstrated at RAND MINES LTD. ERPM mine as described in the Appendix I trip report. At pH 4.5, a 95% plus water recovery was achieved, and the iron content was reduced from 6.0 ppm to 0.06 ppm. WILMOTH and SCOTT (1976) found that Fe^{2+} ions could be removed from 64 ppm to 0.5 ppm in their tests of R.O., also yielding a product water at pH 4.5.

    A summary of the results achieved by WILMOTH and SCOTT (1976) is provided in the following table:

Chemistry Analyses Illustrating Effluents from Various Processes to Treat AMD

Sample	*Cond*	*Acid*	*pH*	*Ca*	*Mg*	*Total iron*	*Fe^{2+}*	*Na*	*Al*	*Mn*	*SO_4*	*Alk*	*TDS*
Example One - Limestone Neutralization: Ferrous(A) versus Ferric(B) Using No Coagulants													
Raw feed A	4,000	610	5.2	360.	110.	270.	260.	480.	5.4	5.9	3,000	12.	4,200

Waste brine	3,600	810	2.9	490.	310.	330.	250.	—	44.	24.	2,800.	0.	4,500
Effluent	17	32	4.5	0.5	0.6	0.5	0.5	—	0.2	0.08	2.2	0.	5
Example Eight - Ion Exchange Treatment (Design Values)													
Raw feed	—	240	3.4	130.	90.	77.	64.	1.0	12.	12.	750	0.	1,300
Cation eff.	—	800	1.9	13.	5.	6.	5.	3.	0.2	0.6	750	0.	800
Anion eff.		0	8.0	13.	1.5	1.2	1.0	20.	0.2	0.3	40	20.	110
Neu. eff.	—	0	7.5	20.	1.5	0.1	0.1	20.	0.2	0.04	50	30.	120

Note: All units are mg/liter except for conductivity (micromhos/cm) and *p*H. Alkalinity and acidity are expressed as $CaCO_3$.

It is noted in the above table that ferrous iron could be reduced using H_2O_2 as an oxidant and limestone from 270 mg/l to 6.2 mg/l, although the same solution with limestone addition and extended aeration reached pH 7.4 and iron was reduced to 0.9 mg/l.

CATALYTIC OXIDATION OF IRON

In Chapter 39 where removal of copper is discussed, a paper by FAULKNER (undated) describes how iron can be catalytically oxidized from ferrous to ferric with the use of SO_2 and activated carbon, even at an acid pH.

CALGON CORPORATION
Activated Carbon Division
Post Office Box 1346
Pittsburgh, PA 15230
(412) 777-8000
William D. Faulkner

KAIDA, et al. (1978) described a bench scale treatment of mine effluent containing iron, copper, Cd, and zinc. The process employs catalytic air oxidation of ferrous to ferric ions using $NaNO_2$, allowing fractional precipitation of ferric hydroxide prior to removal of other metals.

Both of these processes are petentially useful.

OCCURRENCE OF MANGANESE IN THE MINE-MILL ENVIRONMENT

Manganese, although not nearly as abundant as iron in rocks and soils, is nonetheless very abundant. Manganese frequently occurs in mine drainage and is often associated with zinc, copper, and silver ores. In South Africa, MnO_2 is used as an oxidant in uranium leaching with the consequence that Mn^{2+} can occur at high levels in uranium plant tailings and raffinates.

The PEDCO (1983) report which lists the findings of analyses of thousands of mine waste, mill tailings, and mine water samples from mines in the U.S.A., leads to the conclusion that manganese is relatively susceptible to the acetic acid leach tests from mined materials used in the EPA's EP leach test criterion for "hazardous waste."

MAREE and DEWET (1980) showed how manganese in the Vaal River suddenly increased in acidified river water from 140 mg/l to 4400 mg/l at Orkney, Transvaal, where it caused a problem in treatment for use as municipal service water. It was suspected at the time that seepage of gold-uranium mill effluents and runoff from manganiferous soils could have been responsible. Since then, manganese levels have dropped to much less than 1 mg/l as a result of advanced, yet simple, water management and practices by mines from which effluents drain into the Vaal River in that area. (Drainage from several mining companies enters the Vaal River upstream of Orkney.)

HILL (1972) reported manganese in mine waters at 1.2-8.0 mg/l, and KUNIN and DOWNING (1971) reported one acid mine drainage flow with 50 mg/l Mn.

At ENOXY COAL, INC., Buckhannon, West Virginia, coal waste is mixed with a carbonate rock to avoid the generation of acid mine drainage. Although the carbonate rock does inhibit the generation of acid, manganese in the carbonate waste rock goes into solution and reaches 30-150 ppm. This manganese is difficult to remove. To precipitate manganese, at a pH of over ten is needed; then the treated water must be pH adjusted to meet effluent pH limits, all of which require expensive reagents according to:

ENVIRONMENTAL SENSITIVITY OF MANGANESE

Manganese is undesirable in the public water supply. Even very low levels, manganese causes staining of plumbing fixtures and ceramic tilework.

The U.S. EPA (1972, 1976) shows a public water limit for manganese of 0.05 mg/l manganese. CANADA (1979a, b) has set a limit for manganese in the public water supply of 0.01 mg/l.

At 1.0 ppm Mn and more, the hatchability of trout eggs has been found to be affected.

The ONTARIO MOE (1979) discussion of the rationale for establishment of Ontario's Provincial Water Quality Objectives does not review manganese. The U.S. EPA and Canada do not define criteria for manganese at which the environment is considered protected. In U.S. EPA (1976), an objective of 100 ug/l Mn is established for marine water. The U.S. EPA does not state whether this is total manganese or soluble Mn.

Information on the toxicity of manganese to aquatic life (both freshwater and marine) is very limited. DAVIES (1981) found that the LC_{50} of manganese for trout in soft water ranged between 14.5 and 30.0 ug/l. The hardwater LC_{50} for 20 cm fish was 116 ug/l.

REGULATORY LIMITS FOR MANGANESE

Quebec has set a maximum limit of 0.05 mg/l for manganese in receiving waters. There does not seem to be any factual substantiation for this limit other than the fact that this limit is the same as for drinking water.

The U.S. EPA maximum permissible limit in marine waters is 0.10 mg/l Mn.

The U.S. EPA (1972, 1976) limit for the public water supply is 50 ug/l.

The South African Bureau of Standards (1971) standard for manganese in drinking water is 0.1 mg/l recommended and 0.4 mg/l maximum allowable.

The SOUTH AFRICAN GOVERNMENT GAZETTE (1962) does not list a limit for manganese in the General Limit for Effluents. However, in the SPECIAL LIMIT which was designed for effluents discharging into a list of specific creeks and rivers (supposedly those that are capable of supporting trout), a limit of 0.01 mg/l Mn was imposed.

During the course of this investigation, the only examples of Mn limits in effluents found were as follows:

MANGANESE-SOLUBILITY CONTROLS

The solubility of manganese in natural water and the predominant dissolved forms to be expected can be effectively summarized by means of Eh-pH diagrams.

FIGURE 16.—Fields of stability of solids and solubility of manganese as a function of Eh and pH at 25°C and 1 atmosphere of pressure. Activity of dissolved carbon dioxide species 100 mg/l as HCO_3^-. Sulfur species absent.

TREATMENT FOR MANGANESE

The solubility diagram for manganese in water inserted above was provided by HEM (1970) and indicates that to precipitate Mn^{+2} as a hydroxide, a pH of close to 12 is needed.

Of the various oxidation states of manganese, only the strongly oxidizing form permanganate and the divalent manganese in manganous ions are soluble in water.

Removal of soluble manganese has been practiced for many years in the treatment of municipal water supplies and industrial process waters.

Treatment technology basically involves the conversion of the soluble manganous ion to an insoluble precipitate. In water treatment, this generally means simultaneous removal of iron since conditions under which high iron levels occur in water supplies are essentially the same as for soluble manganese. Removal of manganese is achieved by oxidation of the manganous ion and by separation of the resulting insoluble oxides and hydroxides of manganese.

Because of the low reactivity of manganous ions with oxygen, simple aeration is not an effective oxidation technique below pH 9, and even above pH 9, the air oxidation reaction is slow according to WELCH (1963).

BORGREN (1962) found that organic matter in solution can combine with manganese and prevent its oxidation by simple aeration, even at a high pH.

OWENS (1963) showed the effect of pH on manganese removal by lime. A reaction above pH 9.4 is required to achieve significant manganese reduction.

Effect of pH on efficiency of manganese removal using lime.
[From Owens (7), courtesy of *Water and Sewage Works.*]

HILL (1972) reported that manganese can be reduced to less than 0.5 mg/l by simple neutralization and precipitation, but no pH values were mentioned. The use of calcium carbonate plus lime for iron and manganese removal from Japanese acid mine waters had proven successful.

The use of chemical oxidants to convey manganous ions to insoluble manganese dioxide in conjunction with coagulation and filtration has been recommended, although BORGREN (1962) reported that this may cause filtration problems. Apparently, the type of manganese flocs produced when strong oxidants are used tends to clog sand filters.

WELCH (1963) reported that manganese oxidation by chlorination may not be effective. OWENS (1963), on the other hand, reported removal of manganese at concentrations as high as 5.7 mg/l with chlorination followed by lime coagulation and rapid sand filtration. Sodium silicate was used as a coagulant aid. This is similar to the process currently in use by the Rand Water Board at their regional water supply treatment plant at Vereeniging, South Africa, which treats Vaal Dam water.

According to HARRIS (1962), effective manganese oxidation by chlorination requires a free chlorine residual of 0.5 mg/l and a dosage of 1.29 mg chlorine per mg manganese oxidized.

The successful use of potassium permanganate as a chemical oxidant has been reported. Addition of 1.5-2.0 mg/l of potassium permanganate reduced 1.0 mg/l of manganese to less than 0.05 mg/l according to HANEY (1964).

Permanganate requirement for oxidation of ferrous iron. [From Willey and Jennings (10), courtesy of American Water Works Association.]

Permanganate requirement for oxidation of manganeous manganese. [From Willey and Jennings (10), courtesy of American Water Works Association.]

$KMnO_4$ was added 30 minutes upstream from the prechlorination point which was followed by lime-alum-sodium silicate coagulation (4-10 hours retention) and rapid sand filtration.

Since iron is generally present, the quantity of permanganate used must include that needed for oxidation of the iron content. The stoichiometric relationship between permanganate required and the quantity of iron and manganese present is shown in diagrams reproduced from PATTERSON (1975) above.

HOLLAND (1964) demonstrated the ability to remove manganese at lower pH with simultaneous removal of iron by permanganate oxidation. The addition of 0.04 mg/l sodium alginate reduced 0.35 mg/l manganese to less than 0.02 mg/l in the filtered supernatant. BORGREN (1962) further pointed out an additional advantage of permanganate over chlorination as the absence of residual taste or odor.

CONSTABILE and PERRON (1971) described the use of a vacuum diatomite filter in conjunction with permanganate oxidation for manganese removal from a municipal water supply. Manganese was reduced from 1.23 mg/l to 0.05 mg/l or less. The unit required 250 lbs. diatomite per million gallons filtered (30g diatomite/m^3).

Permanganate may be used indirectly for manganese removal in the manganese greensand filter method. The filter is a combination of New Jersey glauconite (greensand), manganese sulfate, and potassium sulfate which results in a filter bed of sand grains containing high oxides of manganese as described by WILLEY and JENNINGS (1963). Upon contact with manganous ions, an oxidation-reduction reaction occurs resulting in the formation of insoluble manganese dioxide which remains in the filter bed. The bed is periodically reoxidized with permanganate, and solids are backwashed from the bed. With this system, manganese was reduced from 1.7 mg/l to zero at pH 7.2 using a pressure greensand system (ALLING, 1963). This plant, with 500-700 gpm (2,700-3,800 m^3/d), cost only a third in capital compared with a conventional aeration, lime coagulation-clarifer-filter-recarbonation system. A permanganate dosage of 13 mg/l was used. The water had a manganese concentration of 13 mg/l manganese. Treatment costs in absolute terms are meaningless because it was so long ago, but these were comparable with lime costs for conventional treatment. This plant was continuously regenerated with periodic backwashing of the greensand filter. Generalized removal capacities for greensand filters are given as 0.09 pounds manganese per ft^3 of filter volume with regeneration requirements of 0.18 lb/ft^3 of $KMnO_4$.

Flow rates of 3 gpm/ft^2 are considered normal by ALZENTER (?).

NETZER, et al. (1975) investigated the use of ozone in conjunction with lime as a manganese removal technique in laboratory studies. The following results were reported by PATTERSON (1975) for solutions of manganous chloride initially containing 94 mg/l manganese:

[57] **ABSTRACT**

A process for removing manganese and chloride ions from an aqueous acidic sulphate solution containing zinc, manganese and chloride ions without removing a substantial amount of zinc ions from the solution includes adjusting the free acidity of the solution if necessary to at least about 0.1 molar. The solution is then treated with ozone to oxidize manganese ions to manganese dioxide, and the ozone treatment is continued after the manganese concentration has fallen to a low level to oxidize chloride ions to chlorine gas. The precipitated manganese dioxide is removed from the solution.

9.0	17	LT 0.1
10.0	0.15	LT 0.1
11.0	LT 0.10	-

Ion exchange has been used for manganese removal, and many advantages are claimed by ALZENTER (?). PATTERSON (1975) pointed out one drawback of ion exchange as its non-selective removal of manganese with other ions. ALZENTER mentions performance of the IX plant over three years during which manganese in feedwater was routinely reduced from 1.7 ppm to 0.10 ppm Mn and less on a regular basis with iron removal from about 50 mg/l to 0.3 ppm Fe.

Brine was used for regeneration of the resin, and manganese remained in solution in the brine presenting a disposal problem. An anaerobic waste stream is necessary for the ion exchange system to avoid air oxidation of manganese in the feedwater with resultant precipitation and clogging of the ion exchange bed.

PATTERSON (1975) points out that the cost of the above processes for manganese removal from wastewaters may be increased by the presence of acids, other oxidizable metals, or organics in the waste stream. He points out that the unit operation costs for coagulation-sedimentation-filtration should be similar to those for iron removal systems. Additional costs are attributable for chlorine (or chlorine dioxide) and chlorination equipment plus lime needed to meet the higher pH.

During the course of this investigation, it was interesting that manganese was not monitored much of the time in effluents. In other cases, manganese removal required special conditions in water treatment.

MOUNT EMMONS, COLORADO

Manganese occurs in the old zinc mine water at 6.5-80 mg/l and in seepage from the stabilized tailings ponds at 400-500 mg/l. Through pH adjustment to pH 10.6, Lectroclear flotation of the precipitate, and multi-media filtration, Mn is reduced to 0.05 mg/l in the treated effluent.

Manganese removal requires a higher pH in the treatment plant than would otherwise have been needed.

Capital costs of this plant were $10 million, and operating costs for the 2000 U.S. gpm capacity plant run $700,000-1,000,000 per year operating at partial capacity.

An alternative means of removing precipitated metals that has been tested with promising results is dissolved air flotation.

GILMAN, COLORADO

Mine drainage from the underground zinc-silver mine located on the mountainside above the Eagle River runs 80-453 mg/l Mn. Originally, the ore was milled underground, and the tailings deposited to a tailings dam alongside the river in the valley below.

For years mine water has been segregated into a stream which requires treatment and one which does not. Treatment comprised raising the pH to 9.6 and settling in underground chambers to decant the water. However, during the 1970's, the Colorado Dept. of Health imposed an NPDES permit in which the maximum allowable manganese discharge is a level of 1 ppm.

The trip report in Appendix I includes reference to testwork by The New Jersey Zinc Company and the Colorado School of Mines Research Institute in which various oxidants were tested.

Although NaOCl was selected as the best oxidant from among $NaClO_3$, $K_2S_2O_8$, and H_2O_2, the amounts required were considered uneconomical in 1973. At that time, the addition of 1 lb. lime per 1,000 U.S. gallons of tailings effluent was deemed to be the best solution if operation of the mine seepage pumps were carefully synchronized with lime addition.

When 64 lbs. $Ca(OCl)_2$ equivalent were added per 1,000 U.S. gallons, manganese was dropped to 0.5 ppm Mn at pH 8.2. The addition of 22 lbs. of $Ca(COCl)_2$ equivalent and 23 mg lime per liter, reduced Mn to 0.9 ppm. Because $Ca(OCl)_2$ costs around $1.43/lb, it was concluded that this reagent would be uneconomical. Addition of 0.56 lbs. lime per 1,000 gal. resulted in a pH of 9.5 and reduced Mn to 1.1 ppm Mn, resulting in the conclusion that lime addition of 1.0-1.5 lbs. per 1,000 gal. would be the logical answer to reduce Mn to below 1.0 ppm Mn--cheap at 1.9 cents/lb lime at that time.

The Colorado School of Mines Research Institute showed that by passing the mine water through a column of crushed pyrolusite--which occurred in a vein in the mine--manganese levels could be dropped from 5 mg/l Mn to below 1.0 mg/l. The adsorption rate was shown to be a function of the manganese content of the feed solution and the retention time in the column. pH did not influence the adsorption rate in the range tested (pH 7.8-8.8). The pyrolusite adsorption of manganese II was found to be self-regerative to a degree. Mn II is adsorbed and in time oxidizes to $MnO_{1.3}$ and then to $MNO_{1.9}$ which is an adsorbent for incoming Mn II in solution. The granules in the column must be treated to restore permeability.

It was found that 1,000 gallons per minute of mine water containing 5 mg/l Mn II, a total of 5,407 m^2 of surface area would be required, or 32.8 tons of 1/2" x 1/4" pyrolusite. Assuming 120 lbs. per ft^3, this would require two 12 ft Ø tanks with 5' high beds of crushed pyrolusite.

It is believed that the pyrolusite adsorption tanks were never installed at the Gilman Mine. It is nonetheless of interest that the laboratory scale tests demonstrated the effectiveness of pyrolusite for Mn II removal from mine water at lower pH without the need for oxidation.

ENOXY COAL, INC.

At ENOXY COAL, INC., coal waste acid mine drainage is inhibited by adding a calcerous carbonate rock waste to the coal waste. This neutralizes any acid that is generated. However, although the AMD is neutralized and iron precipitated, manganese contained in the high $CaCO_3$ neutralizing waste goes into solution.

It was found that in solutions containing low levels of iron and up to 100-130 mg/l Mn II, it is very difficult and expensive to precipitate manganese. Randol International Ltd. recommended to ENOXY COAL that they test the HDS process.

THE HDS PROCESS

HERMAN (1984) of the BETHLEHEM STEEL CORP. showed at the Randol Workshop on Water Management that manganese can effectively be precipitated from acid mine drainage at a pH around 6.8 through the use of the high density sludge HDS process. In this process, lime is mixed with recycled sludge prior to being added to incoming acid mine drainage.

Manganese can be precipitated in this way even in the absence of iron.

A precipitate sludge is generated which lends itself to stabilization for landfill disposal by addition of a pozzolon. Apparently, if precipitated in the absence of iron, manganese redissolves readily unless stabilized in this manner.

More details on this process are available from:

RØSSING URANIUM LTD.

Manganese dioxide is used as an oxidant to dissolve uranium from RØSSING ore using a sulfuric acid leach at elevated temperature. Solution in the uranium tailings contains

2,000-2,500 mg Mn II/l at pH around 2. The tailings impoundment is porous, and seepage is collected by interceptor trenches. The natural rock and sediments contain carbonates which help to neutralize seepage solution. It is of interest that the seepage collected has pH 6.7, and the manganese level has dropped to 1100 ppm Mn.

In inspecting the trench faces, it is interesting to observe manganese oxide precipitating in the strata. Clearly, manganese oxides and hydroxides act as an excellent adsorbent for manganese from solution, even at relatively low pH.

Natural soils form good geochemical adsorbents for manganese: this property could undoubtably be exploited in special cases.

ORKNEY MUNICIPALITY, SOUTH AFRICA

River water from the Vaal River, when treated for use as municipal water by the municipal water treatment plant at Orkney (or Klerksdorp), Transvaal, was found in 1976 to be higher in manganese than the drinking water standard.

The National Institute for Water Research of the CSIR investigated various ways to remove manganese from this water. Their investigation concluded that:

1. The oxidation rate of Mn II is pH dependent.

2. The reaction Mn II and O_2 = MnO_2 is autocatalytic.

3. Measurable oxidation of Mn (II) by O_2 occurs only at pH in excess of 8.5.

4. Manganese is effectively removed from solution by adsorption on MnO_2. This adsorption is also pH dependent, requiring a pH of at least 7.7 to proceed at any pace.

5. Adsorbed metal ions on hydrated oxides are released when the pH is dropped.

6. The higher the amount of Cl_2 added, the faster the removal of manganese at around pH 7.

7. At 15 mg/l Cl_2 addition, the rate of Mn (II) removal is enhanced by increasing pH just one unit from 7 to 8.

8. Addition of 500 mg/l MnO_2 at pH 7.5 has a dramatic increase on removal of Mn (II) ions from solution.

9. In the presence of Cl_2, just 0.66 ppm $Mn^{+/}$ increases the rate of Mn II removal by 100%.

Eventually, it was found that allowing MnO_2 to coat filtersand in the filtration plant makes it possible to effectively precipitate manganese from the raw municipal water when it is filtered. The NIWR report with details has not been published. However, industry can approach the NIWR for help on manganese removal problems.

High manganese has been found in several other South African raw municipal water supplies.

VAAL REEFS EXPLORATION AND MINING CO. LTD., ORKNEY, TRANSVAAL

Manganese is used as an oxidant in acid uranium leaching on the Witwatersrand including Vaal Reefs. Typical uranium plant raffinates contain 1670 ppm Mn. Effluents from various Vaal Reefs plants are currently treated by mixing them with tailings pulps and adding lime to raise the pH to 9.5. A considerable amount of iron in the form of raffinate (730 ppm Fe^{2+}, 500 ppm Fe^{3+}) is added. This requires 10-12 Kg lime per ton which, at Vaal Reefs, costs R7.76 million/year in lime costs alone to yield a tailings dam decant solution with less than 1 ppm Mn.

Effluent neutralization in this way costs R0.80-R1.00 per ton ore treated which is a sizable percentage of total metallurgical costs, but allows zero discharge and recycle of all water that can be reclaimed.

Since the implementation of effluent neutralization at Vaal Reefs, the manganese level in the Vaal River water has been reduced to less than 1 ppm in the vicinity of the huge metallurgical complex.

RAND MINES LTD., ERPM SEEDED SLURRY R.O.

At the Hercules shaft of the ERPM Mine on the eastern Witwatersrand, a mine water was desalinated on a test basis in 1984 to demonstrate the seeded slurry reverse osmosis process.

Manganese levels were reduced from 8 mg/l in feedwater at pH 4.5 to 0.5 ppm Mn in the product water. This demonstrated a much higher tolerance to manganese than can normally be tolerated by membrane desalination processes, and a high water recovery in excess of 95%. More information on seeded slurry reverse osmosis is available from:

Tom Wolfe

Fundamental to the success of seeded slurry reverse osmosis is the availability of a new cost effective tubular R.O. unit referred to in the chapter on reverse osmosis.

BUREAU OF MINES, PITTSBURGH, JET AERATOR

ACKMAN and KLEINMANN (1984) described a new in-line aeration and treatment system for acid mine drainage. The principle is to add NaOH solution via a nozzle to the acid mine drainage via a jet pump followed by a static mixer ahead of discharge to a settling pond.

Although NaOH is more expensive than lime, in this case the equipment simplicity would enable significant capital cost savings.

Manganese was dropped in demonstration runs by 50% from a level of around 70 mg/l, at pH 4-6, and almost quantitatively from the same solution at pH 7-9.

Commercial jet pumps for the purpose are now available as described in Chapter 24 on acid mine drainage treatment. More information is available from:

ARGO TUNNEL TEST, WANNAMAKER CONTINUOUS CONCENTRATOR

The Colorado Dept. of Natural Resources, Dept. of Mine Land Reclamation, demonstrated a device known as the Wannamaker Continuous Concentrator in 1981 to treat ARGO TUNNEL acid mine drainage containing 108 ppm Mn.

The precipitate was recirculated through the Wannamaker Continuous Concentrator as described by HOLM and SIMPSON (1981).

In this test, manganese was reduced to 0.65 ppm at pH 9.2 and to 0.005 ppm at pH 9.8. The proposed water standard was 1.1 ppm Mn.

More information is available from:

COLORADO DEPT. OF NATURAL RESOURCES
Mined Land Reclamation Division

J. David Holm

Randol International Ltd. believes that the effectiveness of manganese removal would be enhanced if the cross-flow filter were to be used in an HDS mode--ie., mixing the filtercake slurry with lime before it contacts the influent water to be treated.

DRY MGO PRECIPITATION OF METALS

SCHILLER and KHALAFALLA (1983) describe a patented process for removal of heavy metals and manganese from wastewater employing a substantial excess of essentially dry powdered reactive MgO as the precipitant. The resulting precipitant settles rapidly to a small volume of solids which is not readily redispersed or redissolved. A water product with low suspended solids can readily be recovered by decantation. More information can be requested from:

S. E. KHALAFALLA

SULFIDE PRECIPITATION

LARSEN and ROSS (1976) showed the effect of addition of lime and then Na_2S to acid mine drainage containing various metals including manganese.

It is of interest that manganese is one of the last metals to be precipitated in this way, and, even after 700 ml solution containing 0.1M Na_2S was added to an AMD sample containing 126.3 mg Mn/l, all manganese had still not been precipitated.

Two-stage process chemically treats mine drainage to remove dissolved metals

H. Peter Larsen and Laurence W. Ross, University of Denver

Fig. 1—Field treatment system for mine drainage

TREATMENT OF MINE DRAINAGE WATERS has fast become a necessity for all mining operations, and regulations governing discharge into local waterways can be expected to become even more stringent. One aspect of mine water treatment—removal of dissolved metals—can be accomplished by a two-stage process developed at the Denver Research Institute (DRI). The first stage of the process treats the waters by lime neutralization to eliminate Fe and Al. A second stage then removes Cu, Zn, Mn, and heavy toxic metals (Hg, Cd, As) by adding sulphide to the waters.

The quantitative effect of both stages of treatment can be predicted by a mathematical description based on the equilibrium relations involved:

$$mM^{+d} + dD^{-m} \rightarrow M_m D_d \downarrow \qquad (1)$$

where M is the metallic cation of charge $(+d)$ and D is the anion of charge $(-m)$.

The removal of dissolved metals by neutralization (stage 1) is predicted quantitatively. Total sulphide addition to achieve removal of specific metals is predicted for stage 2.

Table 1 provides the set of numerical constants used to describe the system mathematically. These values were selected from the literature as yielding the best approximation to measured results. Butler[1] has pointed out that K_{sp} values are often so small that they are outside the realm of realistic measurement. Therefore, a set of values that gives consistent results is all that is needed.

DRI process successful in field studies

Field investigation for the DRI process included erection of a treatment pond beside Mineral Creek in the

Fig. 2—Results of sulphide addition to Idaho drainage sample

Fig. 3—Results of sulphide addition to Montana drainage sample

Regulatory authorities in most industry centers are "paranoid" about mercury and not without some justification. Mercury poisoning has resulted in an extremely unpleasant and even fatal illness in some of the people who worked with mercury in the past and also to people who ingested mercury via the food chain. Memories of contaminated tuna and the tragic Minamata Bay accident in Japan which resulted from an industrial discharge of an effluent containing mercury are still fresh in our minds.

Mercury can be a problem in the workplace when allowed to build up in recirculating metallurgical process solutions; for example, in zero discharge gold and silver recovery operations. Restrictions on mercury in mine-mill effluents are very strict indeed to protect aquatic life.

Mercury occurrences in nature are common especially in and around mineralized zones, particularly of volcanic origin (epithermal), gold and silver deposits and base metal deposits. Mercury also occurs as a primary resource and is often enriched in soils around mineralized zones even where base metals may be only weakly enriched.

During the late 1960's and early 1970's, mercury was considered to be a likely pathfinder element in mineral exploration. Numerous techniques were developed to analyze mercury in soils and soil gas, but the ultimate result was that mercury anomalies occur so much more frequently than mineral deposits that this technique has not become widely applicable.

Mercury probably occurs more often than it has been recognized in the effluents of mine-mill complexes. There are reliable quantitative ways to monitor the air in the work environment, but the EPA limits for mercury in water are so low that they are well below the best analytical techniques.

OCCURRENCE OF MERCURY IN THE MINE-MILL ENVIRONMENT

Based on data contained in the PEDCO (1983) report to the EPA, mercury levels in mine and mill effluents and leachates seldom exceed one ppm and are usually in the ppb range or less. A summary of their data for mercury has included below.

Historically, mercury was extensively employed for amalgamation recovery of gold from both placer and lode deposits but its use has now been almost entirely replaced by other processing methods. Mercury poisoning was apparently not all that uncommon among workers who operated amalgamation plants or amalgam treatment facilities. Even in recent times, amalgamation was used at the DUVAL CORP.'s Battle Mountain operation and at HOMESTAKE's Lead operation. At Lead, amalgamation of slimes has been entirely replaced by cyanidation leaching and carbon in pulp. At Battle Mountain, amalgamation has been replaced by the installation of jigs ahead of cyanidation to catch coarse gold. There are

still numerous plants in South America and South Africa which employ amalgamation to treat gravity concentrates as do small placer operations in Alaska, although in South Africa the trend is increasingly toward intensive cyanidation and electrowinning.

Mercury dissolves in alkaline cyanide solution with the result that if solutions are to be recycled, mercury levels can build up despite the fact that it generally follows gold through zinc dust precipitation into the precipitate or also through carbon adsorption and electrowinning.

Mercury is consequently recovered as a minor by-product at several gold mining operations including the CARLIN GOLD MINING CO., Nevada; PUEBLO VIEJO, Dominican Republic; PINSON GOLD MINING CO., Winnemucca, Nevada; and at FREEPORT GOLD, Elko, Nevada, to name a few.

When mercury is present in a milled ore, it may build up in solution as process water is recycled. If zinc precipitation is used, then mercury must be retorted from the precipitate and recovered prior to smelting. If carbon adsorption processes (either carbon columns for solution or CIP for slurries) are to be used, then mercury can report in the plant around the carbon regeneration kiln, the electrowinning cells, and over the elution vessels, as well as around the steel wool cathode smelting operation. In metallurgical solutions, mercury levels are likely to increase until an equilibrium level is reached and maintained. Interestingly enough, it is not only epithermal deposits that contain mercury. The Witwatersrand fossilized placer deposits also contain low levels of mercury along with other metals, but studies by the Chamber of Mines of South Africa have concluded that these present no cause for alarm from a safety or environmental standpoint.

In California, where PLACER SERVICES, INC. employs a dredge to rework an old placer deposit by digging deeper, amalgamation is used for gold recovery. However, more mercury is recovered than lost in the process. In this case, previous operations left mercury in their tailings which is now being recovered in PLACER SERVICES' more efficient gravity process.

Based on the PEDCO (1983) report data, mercury in copper, lead, zinc and other operations is generally present at very low levels. This data is relatively "spotty," but it is the best currently available. In some gold cyanidation operatons, the mercury levels undoubtably reach levels in the tens and likely in the hundreds of ppm.

PEDCO (1983) DATA SUMMARY - MERCURY

URANIUM - NEW MEXICO

All minewater and both acetic acid and water leach of solids are reported as less than 0.0005 mg/l Hg.

URANIUM - WYOMING

Surface mine waste acid leachate reached a maximum of 0.046 mg/l and a minimum of less than 0.0001 mg/l Hg. Acid leaching of low grade ore containing 0.046 mg Hg/Kg ranged between a maximum of 0.014 mg/l and a minimum of 0.0001 mg/l. All other leachates ranged between 0.0008 mg/l and less than 0.0001 mg/l Hg.

URANIUM - OTHER

Mercury levels are somewhat higher in this district as illustrated by the following summary although still well below the criterion of 0.2 mg/l.

Levels of up to 0.027 mg/l Hg were encountered in the aqueous leachate from surface mine waste and 0.046 mg/l Hg in the acid leachate from underground mine waste, and minewater pond liquid and untreated mine water are shown at less than 0.0076 mg/l or 8 ppb Hg.

WESTERN LEAD/ZINC DISTRICT

The average mercury in underground mine waste is shown as 0.34 mg/Kg with less than 0.00005 mg/l Hg in the acid leachate and an average of less than 0.0051 mg/l in the aqueous leachate. The maximum level in mine backfilled tailings aqueous leachate was 0.048 mg/l.

EASTERN LEAD/ZINC DISTRICT

Tailings pond liquid varied from less than 0.0002 mg/l to 0.0018 mg/l Hg. Tailings pond settled solids ranged from 0.01 g/t Hg but maximum acid leachate and water leachate reached 0.032 and 0.102 mg/l respectively. Averages were 0.0077 mg/l and 0.0303 mg/l.

MISSOURI LEAD/ZINC

Only one leachate, the aqueous leachate from tailings pond settled solids, exceeded 1.0 ppb at 0.0011 mg/l Hg. All the rest were very low, in the range 0.0002-0.0008 mg/l.

MOLYBDENUM

Tailings pond liquid and untreated mine water are listed at less than 0.0076 mg/l Hg, but the report does not specify how low.

NEVADA GOLD/SILVER DISTRICT

Not surprisingly, mercury reaches somewhat higher levels in leachates from gold and silver milling operations, but considering the known association between mercury and gold-silver orebodies, it was surprising that the leachable levels were not even higher.

Aqueous leachate from surface mine waste ran 0.022 mg/l Hg. Tailings pond liquid interestingly enough varied between 0.358 and 0.526 mg Hg/l, probably reflecting mercury leached in the cyanidation process. Even tailings pond solids run between 0.0025 mg/l and 0.0415 mg/l Hg.

Even though the EP toxicity test criteria were not exceeded by the leach test, decanted tailings pond liquid exceeded the EP leach test criteria for mercury in some cases.

OTHER GOLD/SILVER DISTRICTS

In this area, leach test results for three samples yielded less than 0.0011 mg/l Hg, but tailings pond liquid ran 0.0423 mg/l, and the acid EP leach test with acid from settled solids in the tailings pond exceed 5.7 mg/l. It is clear that from one gold mining district to another, there are major changes in mercury levels and also in the amount of mercury that is acid and water soluble.

TACONITE DISTRICT

Even in the taconite district, mercury levels in ore are higher than one might expect at 0.0013 mg/l in acid leachate. Although not a high level in itself, the acid leachate exceeds 1 ppb.

In the course of this investigation, it was surprising how seldom mercury is monitored on a regular basis; it having been determined in the past (it is assumed) that mercury levels are of no consequence in the effluents. The only references to mercury monitoring in mine and mill effluents encountered are as follows:

	Effluent Hg (ppb)	Permitted Hg (ppb)
Kidd Creek Mines, Timmins		
- Underground Mine Drainage	LT 1	
- Treated Mine Drainage in Holding Pond	LT 1	
- Recycled Minewater	LT 1	
- Kidd Creek Water After Mixing with Treated Water	LT 1	
Mount Emmons Operation, Climax Molybdenum Division		
- Maximum Permissible Limit (Daily)	0.05	0.05
- Measured in Treated Water Discharge	LT 0.20*	

	MERCURY	
	Effluent Hg (ppb)	Permitted Hg (ppb)
Kidd Creek Concentrator, Timmins		
- Tailings Decant After Lime Treatment	LT 1.0 ppm	

* Detection Limit

Most gold and silver recovery operations located in the western U.S.A. are "zero discharge" operations and consequently, effluent limitations do not apply as there is no effluent. These operations would be expected to have somewhat higher mercury levels in their recycled process solutions.

BYCROFT, et al. (1982) reported on mercury contamination of the Lerderberg River, Victoria, Australia, from an abandoned gold field. This paper was not obtained but could be requested from the authors at Monash University, Clayton.

PATTERSON (1975) refers to observations that caustic soda manufactured by chloralkali processes that use mercury may contain "very high" levels of mercury. Literature references report mercury levels of 0.2-150 mg/l in caustic solutions. Caustic from Swedish chloralkali plants contained an average of 3.26 mg/l Hg. Considering the very low levels of mercury allowed in effluents, even the possibility of levels of this magnitude in caustic soda reagents must be taken into account where caustic soda is used for pH adjustment. The addition of 0.3 lb. caustic per ton of solution, for example (150g/t), would add 1 ppb Hg to the effluent which is of the order of the maximum level permitted in mill effluents.

It is possible, but not confirmed, that environmental concerns about mercury losses in chloralkali plants may well have resulted in steps to reduce levels in caustic soda product since PATTERSON (1975) reported the results.

REGULATORY LIMITS FOR MERCURY IN EFFLUENTS

Objectives and maximum permissible limits for mercury in receiving waters are listed below. It is interesting that the MINISTRY OF THE ENVIRONMENT OF ONTARIO (1979) has set two objectives. First is a concentration of 0.2 ug/l Hg of total mercury in filtered water and second, a maximum level of 0.5 ug/g Hg in whole fish (wet basis) for the protection of aquatic life and fish-consuming birds as well as the human consumer.

Compiled by NORANDA

Hg (ug/L) MERCURY

TABLE

MERCURY

The U.S. EPA criteria objective for mercury in receiving waters for the protection of the environment has been set by the U.S. EPA (1980) at 0.00057 ug/l with a maximum permissible concentration of 0.0017 ug/l.

Since the detection limit of most commonly used analytical measuring instruments is much higher than this, the U.S. freshwater criteria are considered unrealistic. The U.S. objective and maximum permissible concentration are also well below background levels in many streams and lakes. The most sensitive detection equipment in common use is the U.V. detection system employed in the flameless atomic absorption cold vapor technique. This method has an accepted detection limit of 0.01 ug/l as Hg. Although the detection limit can be decreased to 0.001 ug/l, accuracy at this level is poor, and at such extremely low levels, there is no way of knowing whether the mercury measured is in fact in the water or introduced from other sources, e.g., adsorption on the walls of the laboratory glassware. Possibly the objective is meant to be regarded as a target with no serious intention of ever meeting it; the basis for the U.S. mercury objective and maximum permissible concentration is not known.

WATER QUALITY CRITERIA FOR MERCURY

Freshwater	Hg (ppb)
U.S. EPA (1980) Max. 24-Hour Average Hg Objective	0.00057

MERCURY LIMITS IN MINE-MILL OPERATING PERMITS

Most of the operations visited did not have a stipulated mercury limit in their effluents because, in most cases, mercury was not deemed to be a problem. The few cases where mercury limits were included in the permit are as follows:

	Hg (ppb)
HOMESTAKE MINING COMPANY, Lead	
- Final Effluent (NPDES)	1.0
HOMESTAKE - McLaughlin Project	
- Treated Runoff Water, 30-Day Ave.	1.0
- Treated Runoff Water, Daily Max.	2.0
AMAX, INC., Mount Emmons	
- Final Effluent After Treatment (NPDES)	0.5

EFFECTS OF MERCURY ON METALLURGICAL EFFICIENCY

RENCO MINES LTD. in Zimbabwe recovers gold by cyanidation and CIP from an ore containing undersirable contaminants which interfere with the process. One of these (MENNE, 1984, personal communication) is bismuth which is believed to interfere with gold adsorption on carbon.

RENCO MINES LTD. adds 200g $HgCl_2$ to the pulp just before it reaches the first agitator. The $HgCl_2$ is added with the cyanide solution at the pump sump between the pulp pre-aeration tanks and the first leach agitator.

The 200g $HgCl_2$ dose was found to be critical. Any less than that, and gold recovery drops off. Any more does not help recovery but adds to expenses.

RENCO MINES LTD. made the fascinating observation that within minutes of being added, the mercury which was added in soluble form cannot be detected in the pulp solution. Of 200g $HgCl_2$ added in the circuit, only 50-70% can be found in the final tails.

Although the precise role of the mercury in gold leach and CIP enhancement is not yet understood, more information may be available from:

A second effect of mercury on gold leaching was referred to at a verbal presentation on gold recovery on the Witwatersrand by P.J.D. Lloyd (recollection only) who then was Research Director of the Chamber of Mines Research Laboratories in South Africa. He presented data which supported his view that gold dissolution by cyanide from Witwatersrand ores was inhibited by the presence of small amounts of mercury in the ore which necessitated a leach residence time long enough to dissolve the mercury before the last of the gold could be brought into solution. Information may be requested from:

DR. P.J.D. LLOYD
Managing Director
EMS Minerals
Post Office Box 585
Bedfordview - Johannesburg
South Africa

The above indicates that the addition of mercury in soluble form may enhance gold extraction, but mercury in mineral form may retard leach kinetics. It must be stated that the latter observation was presented more as a tentative hypothesis than a fact.

ENVIRONMENTAL SENSITIVITY - MERCURY

The biologically significant form of mercury is methyl mercury which is very much more toxic to aquatic organisms than inorganic mercury. According to JOHNELS, et al. (1967) and KAMPS, et al. (1972), the bulk of mercury found in fresh water fish occurs in the form of methyl mercury. Methyl mercury may also be demethylated by bacteria in sediments according to SPANGLER, et al (1973).

Methylation of mercury in the environment occurs by at least two mechanisms as described by WOOD, et al. (1968) and LADNER (1971).

Administrative guidelines for fish for human consumption promulgated by the U.S. Food and Drug Administration and the Canadian Food and Drug Directorate are set a 0.5 ug/g mercury in edible portions. There is no evidence according to ONTARIO (1979) that concentrations of 0.5 ug/g mercury in fish have any effect on the fish themselves. Concentrations of mercury in fish that have been killed by chronic exposure to methyl mercury ranged from 9.5 to 23.5 ug/g Hg according to ONTARIO (1979).

ONTARIO (1979) provides a table showing the results of a series of toxicity studies which demonstrate that most organic mercury compounds are more toxic than inorganic mercury salts.

ONTARIO (1979) concluded that fish-eating birds should be protected if the concentration of total mercury in whole fish does not exceed 0.5 ug/g.

Bioaccumulation of mercury occurs in many fish, bird, and other aquatic species, and some examples are cited in ONTARIO (1979).

With the exception of some of the most severe cases of mercury pollution, aqueous mercury concentrations, U.S. EPA (1980) and NRCC (1979), are generally well below levels which would affect the wellbeing of aquatic and marine life.

According to HEIT and FINGERMAN (1977), the method used by the EPA to extrapolate to the objective figure and the MPC provided an erroneous result. The figures must be erroneous considering the bountiful fish populations that thrive in water with significantly higher mercury background levels.

Crayfish are apparently particularly sensitive to mercury with LC-50 of 50 ug/l and LC-50 of 250-1,000 ug/l reported by two papers which is about 2,500 times higher than that reported by another worker.

The second most sensitive species listed by the U.S. EPA is Daphnia magna which was observed to have a 48-h LC-50 of 5 ug/l as Hg_2Cl_2 (data from BEISINGER and CHRISTENSEN (1972)). The LC-50 value found in their study is 2,940 times greater than the MPC.

Rainbow trout LC-50 value of 250 ug/l Hg is tested as Hg_2Cl_2 compared with 20 ug/l for methylmercuric chloride according to the U.S. EPA (1980). Rainbow trout are generally considered to be one of the most sensitive fish species, and their LC-50 values are 147,000 and 17,000 greater than the MPC which suggests that the MPC derived by the EPA (0.0017 ug/l) is unrealistic.

Several studies showed that no toxic effects were observed at the Environment Canada 0.1-0.2 ug/l total mercury objective level, but if 10-20% of the total mercury is in a methylated form, then bioaccumulation could potentially occur. However, methylmercuric chloride concentrations of less than 0.01 ug/l Hg do not appear to cause great increases in fish mercury concentrations over background levels.

It is concluded that in arid regions where metallurgical operations can be operated on a zero discharge basis, mercury is of less concern environmentally than worker exposure to mercury vapor derived from processing solutions containing levels of mercury that have become elevated due to water recycling.

In areas where effluents must be discharged, the Canadian MPC and objective for 24-hour average levels of mercury are reasonable, whereas the U.S. EPA objective is both unenforceable for lack of suitable analytical equipment and unrealistic, being not supported by environmental evidence.

Even if methods could be devised to detect mercury at the EPA objective levels, there are no known processes that can reliably remove mercury from water to the levels cited.

The U.S. EPA marine criteria for MPC and 24-hour average concentration (3.7 and 0.025 ug/l) are based on the results of toxicity tests rather than bioaccumulation potential. Industry observers find these limits scientifically defensible as opposed to the freshwater criteria.

Generally, the 24-hour average objective of 0.025 ug/l is close to typical background levels which suggests that little if any addition to the environment over a long period of time would be permitted although, of course, the oceans have such a large volume that they can tolerate significant additions before the average background level would be impacted.

The U.S. Marine MPC of 3.7 ug/l is in line with toxicity test results and should not be exceeded.

Ultimately, objectives may have to distinguish between methylated and inorganic mercury levels in effluents.

TREATMENT FOR MERCURY REMOVAL

1) Selective Leaching: Gold and Silver Cyanidation

The Bureau of Mines of the U.S. Dept. of the Interior has conducted research into the question of mercury in gold and silver cyanidation solutions and pulps. STAKER, et al. (1983) investigated selective extraction of Au and Ag from a

low-grade Au ore containing Hg. Gold and silver were extracted from the ore in cyanide slurries, and mercury extraction was suppressed with sodium or calcium sulfide. Maximum Au extraction and minimum Hg extraction were obtained using solutions containing 0.34 lb. NaCN/ton solution. Increasing the cyanide concentration increased the mercury extraction without increasing gold extraction. Mercury extraction from the ore was suppressed with 0.5-2.9 lb. CaS/lb. Hg in the ore. Gold to mercury ratios of 100:1 to 400:1 were obtained in the leach solution and on the activated carbon in a CIP circuit.

The above is potentially very significant, especially in low-grade ores in the western U.S.A. which may contain, for example, 2-3 g Au/t with 5-15 g Hg/t. During cyanidation, 10-30 percent of the mercury is extracted along with Au and Ag, and once in solution, mercury follows gold or silver through the process requiring extra precautions in the plant.

Mercury vapor may cause health hazards in the electrowinning, retorting, and carbon reactivation as well as carbon elution steps.

The USBM process to inhibit mercury dissolution is potentially useful in that mercury then stays in the tailing solids. However, careful scrutiny of the effect of CaS addition on cyanide consumption, gold and silver leach rates and efficiency, and adsorption characteristics on activated carbon would be necessary before employing this process.

Further information on progress in this direction and reference to commercial plants that employ this process would be available from:

W. L. STAKER
Salt Lake City Research Center
Bureau of Mines
U.S. Dept. of the Interior
Salt Lake City, UT 84108
(801) 524-6100

For applications where effluents must be discharged for water balance considerations, the question remains whether inhibition of mercury leaching would be adequate to keep mercury in effluents down to levels that would meet the regulatory requirements.

MERCURY REMOVAL FROM GOLD MILL SOLUTION/EFFLUENTS

In the course of this investigation, not one case was encountered where mercury is deliberately removed from a process solution stream or an effluent prior to discharge.

However, mercury is involuntarily recovered as a byproduct by the same extraction process as is used for gold and silver recovery. Examples of such operations are:

Zinc Precipitation - Retorting
Rosario Dominicana, Pueblo Viejo, Dominican Republic
Carlin Gold Mines, Carlin Nevada

Carbon-in-Pulp - Elution - Zinc Precipitation Retorting
Freeport Gold Company, Elko, Nevada

Carbon in Pulp - Elution - Electrowinning - Retorting of Steel Wool
Pinson Gold Mining Co., Winnemucca, Nevada
Getty Mercur Gold Co., Toelle, Utah

It is believed that Harrison B. Salisbury of the Dawson Metallurgical Laboratories has conducted research into ways to remove metals such as mercury and thallium from gold leach solutions.

DAWSON METALLURGICAL LABORATORIES
5217 Major Street
Murray, UT 84107
(801) 262-0922
Harrison B. Salisbury

Several other methods have been employed or are under development to remove mercury from industrial effluents, mostly on a smaller scale:

Precipitation
Ion Exchange
Chelating Compounds
The Devoe-Holbein Process
Coagulation
Reduction to Metallic Mercury and Filtration

PRECIPITATION

In industrial applications, sulfide addition to precipitate mercury sulfide is commonly used. This may be combined with flocculation and separation by gravity settling, filtration, or dissolved air flotation and is also the basis for keeping mercury out of cyanide solution in the leaching of gold and silver from mercury-rich ores. Sulfide precipitation was discussed by BOUVENC (Undated).

PATTERSON (1975) points out that for high initial mercury levels, sulfide precipitation will achieve 99.9% removal at alkaline pH but even with filtration or activated carbon polishing, minimum effluent mercury achievable by sulfide precipitation appears to be 10-20 ug/l. Most effective precipitation appears to be in the near neutral pH range as far as minimizing sulfide dosages according to PERRY (1974).

In addition to the lack of capability to reduce mercury below 10 ug/l, other drawbacks of this method include: 1) formation of soluble mercury sulfide complexes at high levels of excess sulfide; 2) the difficulty of monitoring excess sulfide levels; and 3) the problem of toxic sulfide residual in the treated effluent according to PERRY (1974).

Although the last two of these obstacles have now largely been overcome, the inability to reduce mercury levels to below 10-20 ug/l does not meet the EPA or Canadian ambient water criteria for protection of the environment.

SULFEX PROCESS

Mercury sulfide solubility in pure water is reported to be 1×10^{-21} by YELIGAR, et al. (1981) making it one of the least soluble sulfides. The Sulfex process, described by YELIGAR, et al. (1981) and SCOTT (Undated), employs an iron sulfide sludge bed in a sludge blanket-type clarifier to precipitate mercury and other metals. In this way, sulfide levels are maintained at a constant concentration regardless of the rate of sulfide demand.

The Sulfex process is patented and, together with the sludge blanket reactor clarifier, is offered by:

THE PERMUTIT CO., INC.
Post Office Box 355
E49 Midland Avenue
Paramus, NJ 07652
(201) 967-6000

To date, the Sulfex process has been employed primarily to treat metal finishing and plating effluents, and no operations are known where it is used to treat metallurgical plant effluents although in principle there are no reasons for it not to work.

BOLIDEN METALL, SKELLEFTHAM PLANT, SWEDEN

Sulfide precipitation is employed by BOLIDEN METALL at their Skellefthamn plant in Sweden to remove arsenic at low pH 3.9 followed by filtration to remove the precipitate and lime addition to the filtrate to precipitate fluoride as CaF_2 followed by settling and decantation. This process is described by BLYTHE, et al. (1981) from which the following schematic diagram is taken showing that mercury in feed solution is dropped by sulfide precipitation from 3 ppm to 50 ppb and further to 10 ppb by lime addition and settling.

Typical residual metal concentrations obtained by full-scale test run (Boliden Metall).

SOURCE: BLYTHE, et al. (1981)

More information on this process, as well as the pitfalls to be guarded against when a complex solution is to be treated, is contained in the project summary by BLYTHE, et al. (1981). Additional insight may be possible from:

BOLIDEN METALL AB

Rolf Sevedberg

D. BHATTACHARYYA
Chemical Engineering Dept.
University of Kentucky
773 Anderson Hall
Lexington, KY 40506-0046
(606) 257-2798

According to BHATTACHARYYA (1985, personal communication), one of the problems is excessive cost at low pH when $SO_3^=$ is present because it consumes expensive sulfide reagent. A second problem is the efficient removal of finely divided sulfide precipitates. It is noted that at the low pH, mercury is removed only to 50 ppb and with subsequent

lime addition, to 10 ppb which more or less confirms the performance noted above for sulfide precipitation.

ION EXCHANGE

Most ion exchange treatments of inorganic mercury involve formation of a negatively charged mercuric chloride complex by adding chlorine to oxidize metallic mercury or chloride salts and removal of the mercuric chloride complex on an anion exchange resin. Most experience, according to PATTERSON (1975), has been with chloralkali plant wastes which contain high background chloride levels. There is some evidence, (PERRY, 1974, and GARDINER and MUNOZ, 1971), to indicate that the best ion exchange results are achieved in two stages with a roughing and a polishing step. Table 56 below from PATTERSON (1975) shows that anion exchange reduced mercury to 1 ppb in some cases.

19 U.S. EPA (1971)

Where chloride levels are low, cation exchange resins are effective. Although information on the cation exchange behavoir of mercury is scarce, Amberlite IRA-120 and Dowex-50W-X8 are both reported by ROESMER (1970) to be effective. Since then, of course, resin manufacturers have undoubtably developed improved resins for mercury removal, and it is recommended that sponsors get in touch with their local ion exchange salesmen for more information.

Resins that contain mercapto groups R-S-H such as polythiostyrene are highly specific for mercuric ions according to ROESMER (1970).

PATTERSON points out that regardless of whether anionic resins are used for mercuric chloride complex removal or cationic resins for mercuric ion removal, the best ion exchange treatment for inorganic mercury appears to yield an effluent with 1-5 ug/l. Most effective treatment results from two-stage treatment at neutral to slightly acidic pH.

Most available data relates to the treatment of inorganic mercury, and there is relatively little information on organic mercurials. However, efficient treatment of methyl mercury acetate has been reported with Dowex A-1 Chelate by MUZZARELLI and ISOLATI (1971) and Ionac SRXL resins by LAW (1971) whose paper is inserted below along with one by FREELAND, et al. (1974) who showed how polyethylamine-modified wool fibers can adsorb mercury as Hg^{2+} from solution. The process is said to be effective on 1 ppm Hg solutions, and effluents with only 0.02 ppm were achieved. Additional information on further progress in this field may be available from:

CSIRO
Division of Textile Industry
Post Office Box 21
Belmont, Victoria 3216
Australia

PATTERSON (1975) refers to the Osaka ion exchange process for mercury removal from acid solution which is available under license using an Osaka resin which achieves, according to GARDINER and MUNOZ (1971), levels as low as 5 ppb Hg. This reference may also include the address of the Osaka Company that markets this process and the resin.

A Swedish company (AKTIEBOLAC BILLINGSFORS-LANGED) has developed an ion exchange system which is similar in concept to the Osaka process. A strong base first stage exchanger is regenerable while the second stage polisher is not. Removal is as the mercuric chloride complex anion, thus requiring pretreatment of mercurous and organic mercury. More information is reported by CHEREMISINOFF and HABIB (1972) and ROSENZWEIG (1971).

WILMOTH, et al. (1979) tested lime neutralization, reverse osmosis, and ion exchange for their effectiveness in removing mg/l levels of ten trace elements from acid mine drainage under typical operating conditions. The contaminants were As, B, Cd, Cr, Cu, Hg, Ni, P, Se, and Zn. Treatment by lime neutralization was very effective in removing As, Cd, Ni, and Zn and ineffective for B removal. Dual-bed (strong acid-weak base) ion exchange was very effective in removing all the trace elements except P and B but including mercury.

Methyl Mercury and Inorganic Mercury Collection by a Selective Chelating Resin

Abstract. *A commercially available chelating resin selectively and quantitatively collects methyl mercuric and inorganic mercuric forms of mercury to the exclusion of all other metals studied, except the noble metals. Both forms of mercury can be collected from pH 1 to 9. Collected mercury is readily eluted with a slightly acid, 5 percent solution of thiourea, and the resin can be reused for many cycles. Selectivity, pH effects, capacity, and elution characteristics of the resin are described. A resin-loaded paper composed of 50 percent resin and 50 percent cellulose shows properties similar to those of the loose resin.*

The purpose of this report is to summarize available tests on a chelating resin, Ionac SRXL (*1*), which should provide new opportunities for analysis and for recovery of mercury from industrial and natural aqueous solutions. Previous studies have shown that the resin is highly selective for gold and platinum metals, but its usefulness for mercury had not been considered (*2–4*). My results indicate that the resin has a high affinity for dissolved mercury in both the methyl mercury and the inorganic forms.

Kuster and Schmuckler, original developers of the resin (*2*), explain the selectivity for noble metals by stating that it will "... bind only ions with the d^8 electronic configuration forming square planar complexes. ... ." They further explain that the resin has redox properties because of double bonds, enabling it to collect a species such as Pt^{4+} which is reduced to the Pt^{2+} and then bound as a square planar complex. The mechanism for Hg^{2+} and CH_3Hg^+ collection has yet to be determined.

The properties of SRXL resin were studied in two ways. Data were obtained with resin as received from the manufacturer and with resin-loaded paper, consisting of 50 percent SRXL resin (−325 mesh) and 50 percent cellulose (*4*). Comparisons were made between the resin behavior in a column and its behavior in the resin paper. All solutions were prepared with reagent-grade chemicals, and tracer studies were performed with the ^{203}Hg radioactive isotope and a NaI(Tl) detector.

Selective collection of noble metals, especially gold, from solutions containing high concentrations of more common metals has been reported (*2–4*). I have found also that the resin quantitatively collects dissolved mercury as methyl mercury or as inorganic mercury from solutions of high common metal concentration. A column of resin, 30 by 15 mm, quantitatively collected 100 μg of Hg^{2+} from 250 ml of chloride solutions of iron, nickel, copper, and zinc in amounts up to 10 g/liter. Radioactive ^{203}Hg was used to determine the completeness of collection (Table 1).

Selectivity tests for mercury in the CH_3HgCl, $HgCl_2$, and $Hg(NO_3)_2$ forms were conducted by filtering solutions containing a mercury salt mixed with various metals through paper disks (3.5 cm in diameter) containing SRXL resin; the solution was passed six times through each disk. The disks were rinsed with dilute HCl solution, dried, and analyzed by fluorescent x-ray spectrography. From solutions containing Fe^{3+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, and Hg^{2+} or CH_3Hg^+, only the mercury was detected on the disks; the instrument conditions were sensitive to less than 5 μg for any one of the metals. Neutron activation analysis of SRXL paper disks which were used to collect gold from solutions containing nitrate or chloride salts of metals failed to show any common metal collection (*4*).

Comparisons with another resin, Chelex 100, reported to have a high affinity for Hg^{2+}, show that the Chelex 100 resin fails to collect the methyl mercury form although it does quantitatively collect Hg^{2+}. A paper specially prepared (H. Reeve Angel & Co.) with the Chelex 100 resin, was compared chromatographically with the SRXL

Table 1. Mercury ion (Hg^{2+}) collection from solutions of high metal concentration.

paper. Metal mixtures including Hg^{2+} and CH_3Hg^+ were placed on both papers and developed under identical conditions. The SRXL paper showed complete separation of all metals examined (Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Pb^{2+}) from the Hg^{2+} and CH_3Hg^+ spot, which always had an R_f value of 0. The common metals showed no tendency to be retained by the paper. The Chelex 100 paper showed some affinity for most of the metals. Some spreading of the Hg^{2+} was also noticed. This comparison emphasizes the fact that the SRXL resin has the ability to discriminate between mercury and base metals instead of merely exhibiting varying degrees of affinity for the different ions as is more commonly observed in ion exchange.

The effect of *p*H on the collection of mercuric chloride, mercuric nitrate, and dissolved methyl mercury by the resin and the resin paper was examined over the *p*H range of 0.1 to 9. The results (Fig. 1) suggest the possibility of separating the forms of mercury in solution by *p*H adjustment. The trends and not the magnitudes are significant because different experimental procedures were necessary depending on whether the resin or the paper was used. Collection times were restricted to avoid quantitative collection as the purpose of this study was to observe differences in diffusion and absorption kinetics.

For the loose resin (Fig. 1A), a 200-ml solution, adjusted to the desired *p*H with dilute HCl and NaOH and containing ^{203}Hg radioactive tracer and 1000 μg of Hg^{2+}, or $CH_3{}^{203}Hg^+$ tracer and 990 μg of Hg as CH_3Hg^+, was shaken with 0.33 g of resin on a mechanical shaker for 2 hours. Portions (3 ml) were taken for the determination of radioactivity before resin addition and after shaking, in each case, to determine the amount of mercury collected by the resin. Although mercury is collected at *p*H > 7, use of the resin is probably best confined to *p*H < 7 as recommended by Koster and Schmuckler (*2*). The lowest collection of inorganic mercury is at *p*H 6. One liter of a *p*H 6 solution containing ^{203}Hg tracer and 100 ppm of Hg^{2+} as the chloride was prepared and passed through a small column (1 by 1.5 cm; 0.75 g) of the resin. The effluent from the column was periodically checked for ^{203}Hg activity. After about 600 ml of the solution had passed through the resin at an initial flow rate of 3 ml/min, a small amount (about 2 percent) of

Fig. 1. Effect of *p*H on the collection of inorganic mercury (○) and dissolved methyl mercury (△), by SRXL resin (A) and SRXL resin-loaded paper (B).

mercury tracer began to come through the column. When the flow rate was reduced to approximately 1.5 ml/min, the mercury collection was again quantitative, and no further escape of mercury from the column was observed for the remainder of the 1000 ml of solution. These observations indicate that the total capacity of the resin is probably the same at *p*H 6 as at the lower *p*H values, but the rate of collection of Hg^{2+} is slower at *p*H 6. Therefore, a slower flow rate will be all that is required for quantitative recovery of inorganic mercury at this *p*H.

For the SRXL paper (Fig. 1B), small disks (1.3 cm in diameter) of the paper were suspended by thread for 24 hours in solutions of various *p*H, each solution containing 1000 μg of Hg as $HgCl_2$ or 930 μg of Hg as the methyl mercuric chloride. The disks were dried, and the mercury content was determined by fluorescent x-ray spectrography.

The sudden decrease in collection of the inorganic mercury at *p*H 6 is apparently the result of a reduction-precipitation reaction occurring on the surface of the suspended disks. The surface of the paper disk turns dark, and a white precipitate forms in the solution around the disk, suggesting the reduction of the Hg^{2+} to Hg^0 and $Hg_2{}^{2+}$ followed by precipitation. An essentially identical curve of the effect of *p*H on behavior, with darkening of the disks and formation of a white precipitate, is also observed in the collection of $Hg(NO_3)_2$ from nitrate solutions containing no chlorides. Filtering solutions of *p*H 6 or greater through SRXL resin-loaded paper results in quantitative recovery of the inorganic mercury. No precipitate formation or darkening of the disks was noticed in the solutions containing the methyl mercury.

The capacity of the SRXL resin for Hg^{2+} was determined by shaking 1-g portions of the resin with chloride solutions at *p*H 1.5 containing 2 g of $HgCl_2$ and 10 μc of ^{203}Hg. Portions were taken at intervals for the determination of radioactivity until no further loss of tracer from solution was observed. The capacity of the resin under these conditions was 540 to 550 mg of Hg^{2+} per gram of dry resin. This compares well with the 488 mg per gram of dry resin found by Koster and Schmuckler for Pt^{4+} (*2*).

A 5 percent aqueous solution of thiourea containing 5 ml of hydrochloric acid per liter will elute gold and platinum metals from the resin, permitting its reuse for many cycles (*5*), therefore this eluent was investigated for the removal of mercury from the SRXL resin. A series of eight cycles of mercury collection and elution were performed with the same 2-g portion of resin. For each cycle, mercury was collected from 100 ml of solution containing ^{203}Hg tracer, and each cycle contained the same amount or more mercury than the one preceding. The 100-ml volumes contained from 100 μg to 1 g of Hg. Tracer activity of 3-ml portions of each effluent showed that the collection was 100 percent at all concentrations. Mercury was then eluted from the resin with 10-ml portions of the 5 percent thiourea solution. More than 90 percent of the mercury was removed with the first 10 ml of eluent in each case, and elution was essentially complete after passing 30 ml through the resin. A rate of approximately 3 ml/min was used for the elution and the collection. After elution of the mercury, the excess thiourea was washed from the resin with distilled water, and the next 100 ml of solution were passed through the resin, starting the next cycle.

Thus the ability to selectively and quantitatively collect the highly toxic methyl mercury as well as inorganic mercuric salts, and the ability to be reused for many cycles, make this resin a very promising tool for attacking both the analytical and the industrial problems of mercury pollution.

Adsorption of Mercury from Aqueous Solutions by Polyethylenimine-Modified Wool Fibers

Graeme N. Freeland, Ronald M. Hoskinson,* and Robert J. Mayfield

CSIRO, Division of Textile Industry, P.O. Box 21, Belmont, Victoria, 3216, Australia

■ When used in a packed column or a standing bath, polyethylenimine-modified wool (PEI-wool) had a substantially greater ability to adsorb mercury (Hg^2) from aqueous solution than unmodified keratin. A capacity of 3.3 meq/g was achieved within 30 min using solutions of 1000 ppm (Hg^2). Sorption from liquours passing through a column was rapid and effective at the 1-ppm level. The sorbed mercury was readily desorbed and the PEI-wool used repeatedly.

There have been several recent reports of the ability of protein fibers to adsorb mercury from aqueous solution (*1–4*), and the possibility of using them in effluent purification processes or for clinical purposes (*5*) has been discussed. Likewise, amine-modified cotton could adsorb mercury from solutions (*6, 7*). Here we report that the adsorptive capacity of wool for mercury (Hg^2) is substantially increased by polymerization of ethylenimine onto the fibers.

Experimental

PEI-Wool. Commercially scoured 64's quality Australian merino wool fibers (40 grams) were immersed (2 hr) in a 0.2% solution of ferrous ammonium sulfate (800 ml) and then squeezed before allowing to dry (48 hr) at 20°C. To the wool was added 0.25% hydrogen peroxide solution (600 ml) and ethylenimine (30 ml) (*8*). [Because of potential hazards from exposure to ethylenimine, it has been recommended (*9*) that protective gloves and goggles be used and that all operations be performed in a fume hood.] The fibers were heated (19 hr) at 50°C under nitrogen, rinsed under running tap water (2 hr), dried as before, and chopped to 1–3 mm lengths in a rotary mill. The uptake of ethylenimine (as bound PEI) was 10% w/w.

PEI-Reduced Wool. Unmodified wool (10 grams) was chemically reduced with 0.5M thioglycollic acid (300 ml) at 50°C for 3 hr, washed with distilled water, dried (100°C, 5 min), and converted to PEI-reduced wool as above. The uptake of ethylenimine (as bound PEI) was 20.2% (w/w).

Adsorption onto Columns of Chopped Wool Fibers. The wool (5 grams) was wet out in water containing 0.01% Antarox C0630 (a polyoxyethylated nonylphenol, GAF Corp.) and the resulting slurry poured into a glass column fitted with a porous plug and stopcock. When the fibers had settled they were equilibrated with solutions at the pH of the test solutions. The test solutions contained 1000 ppm Hg^2 (as $HgCl_2$ or a combination of $HgCl_2$–NaCl, Table I) and adjusted to various pH values with NaOH or HCl. Test solutions were admitted at the rate of one bed volume/min. The column effluent was collected in fractions and their mercury concentration measured.

Adsorption onto Wool in Standing Bath. The wool (5 grams) was stirred in a glass beaker with a solution (1 liter) adjusted to the required pH, containing 1000 ppm Hg^2 (as $HgCl_2$ or $HgCl_2$–NaCl, Table I) for prescribed periods.

Capacity of Wool Fiber Beds. Here the capacity of the beds has been expressed as milliequivalents of mercury per gram of wool (meq/g). For adsorption onto columns it was the amount of mercury adsorbed by the bed when its concentration in the column effluent reached 1% of the influent concentration. For adsorption onto wool in standing baths it was the amount adsorbed from the liquors after the prescribed period, and the value was calculated from the decrease in mercury concentration of the bath liquor. All adsorption measurements were made at 20°C.

Mercury Analysis. This was by atomic absorption spectrophotometry. Separate procedures used for solutions containing 1–1000 ppm (*10*) and up to 1 ppm Hg^2 (*11*) were essentially as described.

Results and Discussion

PEI-Wool. Protein fibers will bind approximately 1% of polyethylenimine irreversibly (*12*). This quantity will increase slightly if the fibers are pretreated with chlorine. By polymerization of ethylenimine monomer onto wool fibers, as reported here, irreversible binding of 10–20% PEI can be achieved. It is not known whether the PEI-wool composite so formed contains the PEI as a physically occluded or chemically grafted component. In the present work, wool treated by the last method has been used as packed beds in columns and in stirred standing baths to examine its potential in both continuous and batchwise mercury recovery processes.

Table I shows that maximum adsorption occurred in standing baths where, within 30 min, equilibrium was established. The capacity of 3.3 meq/g is of the same order as that of many granular ion exchangers. Even in solutions containing 10% NaCl, the adsorption of 1 meq Hg^2/g was still significant and may indicate that PEI-wool could

[a] S with a numerical subscript refers to adsorption in a standing bath for the indicated period (min); C refers to a column adsorption. [b] From (*1*).

have practical advantages in adsorbing mercury from electrolyte solutions (*13*).

In column adsorption tests, where the contact time was 1 min, the capacity was lowered slightly to 2.4 meq Hg^2/g at pH 7, indicating that adsorption was a rapid process. Sorbed mercury was quantitatively recovered by extracting the PEI-wool with *N* HCl (50°C, 15 min) or with citric acid solution (1%, pH2, 40°C, 15 min). The wool that was stripped in this way could be reused, an adsorption capacity of 2 meq/g persisting after 15 cycles.

Adsorption onto columns was effective when low concentrations of mercury were used. When 500-bed volumes of liquor containing 1 ppm Hg^2 (pH 6) were passed through the column (1 bed vol/min), the concentration in the effluent did not exceed 0.02 ppm. Greater efficiency could be expected from longer contact times in the column.

When we consider the pH range 2–7, we note that modification of wool with PEI changes the pH of maximum adsorption from 2 to 7; corresponding differences in the adsorption mechanisms might be inferred. Probably, at pH 2, the association of protonated amino groups with anionic mercuric complexes such as $HgCl_3^-$ or $HgCl_4^{2-}$ occurs (*1*). At pH 7, the adsorption probably involves chelation of Hg^2 with ligands located in both the PEI (*14*) and the wool.

PEI-wool appears to have a mercury adsorbing capacity exceeding cross-linked PEI-cotton (*6*) by a factor of 100. Although strict comparisons have not been made its rate of adsorbing mercury seems substantially greater than that reported for the modified cotton (*7*).

PEI-Reduced Wool. Ethylenimine was polymerized onto thioglycollate-reduced wool in the expectation that the chemically modified fibers, released from the restraint of protein disulfide bonds, would swell more readily in aqueous media. An increased PEI add-on and correspondingly improved mercury adsorption might then have resulted.

Practically, the amount of PEI formed in reduced wool was double that formed in native wool. Only minor increases were observed in the mercury-adsorbing capacity of PEI-reduced wool, consequently no advantage can be seen in using wool in the reduced form.

Removal of Mercury from Aqueous Solutions by *N*-(2-Aminoethyl)aminodeoxycellulose Cotton

Stephen L. Snyder and Tyrone L. Vigo

Southern Regional Research Center, Agricultural Research Service, U.S. Department of Agriculture, New Orleans, La. 70179

■ *N*-(2-Aminoethyl)aminodeoxycellulose cotton (AEAC) was prepared in yarn form by reaction of ethylenediamine with chlorodeoxycellulose. The adsorption of mercuric ion by AEAC (degree of substitution 0.4) was studied over a wide range of concentrations. In the concentration range 0.5–43 g/l., the adsorption of mercuric chloride follows the Freundlich relationship, $\log_{10} x = 0.21 \log_{10} C + 2.7$, where x is the mg of mercuric chloride bound per gram of AEAC and C is the residual concentration in g/l. At concentrations in the range of 3.1–0.6 ppm, 100 mg of AEAC removed about 90% of the mercury present in 200 ml of solution, in a single equilibration. The results of this study suggest the possible use of AEAC as an agent for the collection of mercury in industrial processes.

The possibility of employing ion exchange or chelating resins as a means of removing heavy metal ions from solution has been explored by a number of workers (*1–5*). However, cost considerations have prohibited the widespread application of this technique on an industrial scale. A possible solution to the cost problem might be to use naturally occurring polymers or agricultural by-products as the basis for the exchange resin. In this regard, Friedman and coworkers (*6, 7*) have shown that mercuric ion is bound in large amounts by certain agricultural by-products and polyamine derivatives.

This investigation concerns the use of cotton cellulose as the insoluble support matrix; however, the same techniques could be readily applied to other celluloses or synthetic polyalcohols. In the study reported here, we have attached an ethylenediamine group to the anhydroglucose unit of the cellulose backbone via chlorodeoxycellulose (CDC) cotton yarn to give *N*-(2-aminoethyl)aminocellulose cotton (AEAC). AEAC very efficiently adsorbs mercury over a broad range of concentrations. Suprisingly, we observed that at very low concentrations (approximately 100 ppb), untreated cotton yarn also removes significant amounts of mercury. This adsorption may be due to carboxyl end groups and trace materials present in native cotton.

Experimental

Materials. Cotton was loose twist 12/3 (tex-151) Pima kier-boiled yarn unless otherwise specified. The phosphorus oxychloride ($POCl_3$), dimethylformamide (DMF), and

CHELATING COMPOUNDS - INSOLUBLE STARCH XANTHATE

Recently a company in Texas, POLLUTION TECHNOLOGY SYSTEMS, INC., has offered a process and a chelating organic product which removes metals including mercury from solution.

The product, DX-2000, is a buffered forty percent active organic material that effectively precipitates complexed or chelated cationic heavy metals from difficult to treat process waters. The vendors claim that the product is effective over a pH range of 3 to 11. Residual heavy metals are claimed to usually be well below local, state, and EPA-NPDES discharge limit permit requirements.

DX-2000 is claimed to be effective in removing metals also in the presence of complexing agents which would normally interfere with most other removal processes. The metal-DX-2000 sludge cake containing 40% solids is claimed to be more stable than metal hydroxide sludges.

Dosages of DX-2000 for metal removal vary from metal to metal as the loading ability of a liter of DX-2000 varies from metal to metal. For example, Mn^{+2} loads 77 g per liter of DX-2000 whereas gold loads to 550 g Au^{+1}, and silver loads to 300 g Ag^{+1} per liter of DX-2000. Mercury loads to 280 g Hg^{+2} per liter of DX-2000.

The manufacturer-vendor does not make claims regarding the level of mercury that can be achieved using DX-2000. In a pamphlet by the same vendor describing the use of insoluble starch xanthate, it is claimed that mercury levels were reduced to 0.7 and 1.0 ppb in two test solutions.

It is not known what the nature of the DX-2000 product is although the same vendor is known also to manufacture insoluble starch xanthate based on technology developed by the U.S. Dept. of Agriculture.

NORTHERN REGIONAL RESEARCH LABORATORY
Agriculture Research Service
U.S. Dept. of Agriculture

Peoria, IL 61604
(309) 685-4011
Robert E. Wing

The insoluble starch xanthate is claimed to have removed mercury from 100 ppm to 1 ppb in one case and from a second solution containing 10 ppm to 0.7 ppb Hg.

The development of insoluble starch xanthate for heavy metal removal (including mercury) has been described by SWANSON, et al. (1973), WING, et al. (1974), GREENBERG and WING (1983), and WING (1983).

The vendor does not release much detail about how its process works as they wish to sell consulting and engineering services as well as product. More information can be obtained from:

POLLUTION TECHNOLOGY SYSTEMS, INC.

Mike Coward
Manager, Systems Engineering

IKEBE (1974) of SUMITOMO CHEMICAL CO. LTD., Japan, described a process whereby heavy metal ions, especially Cu^{2+} and Hg^{2+}, are sequestered with a dialkyldithiocarbamic acid and are treated with NaOH and Na_2S to produce a scum of CuS and PbS separating the sulfide scum by either precipitation or flotation and regenerating the dialkyldithiocarbamate ion which is then recycled "quantitatively." The use of NaOH in this process improves the efficiency of separation by preventing the formation of colloidal CuS. Thus, $Cu[S(S)CNEt_2]_2$ was suspended in one litre water, and two equivalents of NaOH was added and stirred. One mole Na_2S/l was added, and the CuS formed was removed by precipitation.

When one equiv. of Na_2S was added, approximately 100% of the $NaS(S)CNEt_2$ was recovered. The light yellow liquor recovered had a pH of 12.8 and contained only 1-2 ppm Cu. When NaOH was not used, the recovered $NaS(S)CNEt_2$ contained about 35% of the colloidal CuS in suspension.

DEVOE-HOLBEIN

Devoe-Holbein has also developed a metal removing process which relies on a "composition" or solid adsorbent to precipitate and remove metals. Examples are cited in their literature in which mercury was removed from 12.0 ppm to 4.8 ppb in one case and from 120 ppm Hg to 1.2 ppb in another. A schematic flowsheet for a process employing Devoe-Holvein compositions has been developed and an association formed with an engineering company to develop a practical process.

More information can be requested from:

DEVOE-HOLBEIN (CANADA), INC.

Telex: 05-821538
Bruce Holbein

Devoe-Holbein has not released data on the costs of the process or their "compositions." It was stated that in experimental quantities, the composition would be expensive. Prices

would be much, much lower if the product were in such demand as to justify mass production.

COAGULATION TREATMENT

Removal of mercury by coagulation has been reported for a variety of mercury-containing wastewaters. Coagulants employed include aluminum sulfate (alum), iron salts, and lime. The process has been applied successfully to both organic and inorganic mercury. In pilot plant tests of alum and iron treatment of inorganic and methyl mercury, inorganic mercury was removed effectively only by iron while neither coagulant provided effective methyl mercury removal according to O'CONNOR (1974).

Treatment data for alum and iron coagulation are summarized in the following table . Effluent levels of mercury achieved by alum treatment range from 1.5-102 mg/l and by iron treatment from 0.5-12.8 mg/l. Iron appears to be better than alum for the purpose achieving a lower effluent limit.

ACTIVATED CARBON

The effectiveness of carbon treatment is dependent on several factors according to PATTERSON (1975). These include the chemical form of mercury in solution, concentration of mercury, dosage and type of activated carbon, as well as contact period. Increasing carbon dosage and contact times improves removal of both inorganic and organic mercury as would be expected and as described by LOGSDON and SYMONS (1973). Organic mercury is more effectively removed than inorganic mercury, and a

review of available treatment data by PATTERSON (1975) and shown below in tabular form indicates that the highest percentage removals (85-90%) result from carbon treatment of more concentrated mercury solutions. However, the lowest effluent mercury results from the treatment of lower initial mercury concentrations although the relative efficiency is less. Thus, carbon treatment of initial mercury levels of below 1 mg/l yields an efficiency of removal of less than 70%, but an effluent mercury of less than 0.25 mg/l. Carbon treatment of initial mercury of 10-100 mg/l yields 90 or more percent efficiency but effluent levels of 1-10 mg/l.

REDUCTION PROCESSES

Inorganic ionic mercury can be converted to the metallic form by reduction and separation by filtration or other solids separation methods. Several reducing agents are available including aluminum, zinc, hydrazine, stannous chloride, and sodium borohydride. PATTERSON (1975) references the use of reductive processes to treat solutions with initial mercury concentrations of 1.8-26 ppm Hg which resulted in final mercury levels in the effluents of 5-830 ug Hg/l.

In gold and silver recovery processes using the Merrill-Crowe process (zinc precipitation), mercury will be reduced as well as gold and silver and ends up in the zinc precipitate. If there is enough mercury present, this necessitates an additional step to retort the zinc precipitated metals to remove the mercury before the gold and silver can be smelted to a dore.

The data provided by PATTERSON indicates that in order to achieve mercury levels below 100 g/l, the use of reductants would have to be supplemented by a second polishing step by one of the other treatment steps discussed in this chapter. For example, where gold plant effluents are treated by ferrous sulfide addition and settling to remove cyanide, chances are excellent that mercury will also be precipitated as a sulfide. If carbon columns are used to recover incremental gold from effluents or recirculating solutions, the likelihood of further mercury removal is also excellent by carbon adsorption. If, in future, anionic ion exchange resins are used to recover gold as a cyanide complex, then possibly a pretreatment with chlorine to destroy cyanide will render the mercury in the chloride complex form suitable for loading onto the resin as well, or mercury may load as the anionic mercury cyanide complex.

A full-scale commercial process based on the reduction of mercury by sodium borohydride is marketed as the Ventron process and is described by CHEREMISINOFF and HABIB (1972) and ROSENZWEIG (1971).

ADSORPTION PROCESSES

RANDALL (1974) tested the adsorptive properties of a wide range of agricultural wastes for the removal of toxic metal cations from synthetic solutions as well as mining and industrial effluent streams with a view to recovering metal values. Several of these wastes were reported to remove metals effectively to "below the levels prescribed by local or federal standards." Rate, selectivity, and capacity of the agricultural substrates for heavy metal cations were measured in the laboratory, and the authors claim very effective

removal of Pb^{2+}, Hg^{2+}, Cu^{2+}, Cd^{2+}, and Zn^{2+}. As with several of the processes mentioned above, this approach was not observed in commercial application although it may be worth further evaluation.

OTHER TECHNOLOGY

PATTERSON (1975) refers to a variety of other processes that are mentioned in the literature. These include solvent extraction with high molecular weight amines, the use of silicon alloys for reduction to elemental mercury (McKAVENEY, 1972), removal by insoluble starch xanthate-cationic polymer complexation (SWANSON, 1973; WINZ, et al. 1974), adsorption onto ground rubber and onto wool at sulfhydryl sites (FREELAND, et al., 1974).

Several of these processes appear promising yet in the course of this investigation, none were found in commercial application ten years after they were announced. It is emphasized that such experimental processes require considerable further development and pilot-scale testing before they could be considered suitable for commercial-scale application.

CONCLUSIONS

There are many treatment technologies available for mercury control. The more effective are summarized in the following table which was assembled by PATTERSON (1975). Among the processes listed, ion exchange, iron or alum coagulation, and activated carbon adsorption have the capability to reduce mercury below 10 ug/l, but the effects of cyanide on performance needs to be determined. The trip report on COTTER CORP.'s Schwarzwalder Mine in Appendix I describes an innovative new ion exchange process that reduces uranium and base metals to extremely low levels. Possibly this system would make further improvement possible in the performance of IX for mercury removal.

Conventional precipitation systems employing sulfide and flocculating aids seem capable of achieving mercury levels of 10-20 ug/l. However, RANDOL INTERNATIONAL suggests that combining the HDS process with ferrous sulfide or Na_2S addition may make it possbile to improve this when treating acid solutions.

Other methods, particularly the reduction process for small-scale use, are capable of producing very low-effluent concentrations of mercury. Many of these methods have not been tested in full-scale operation.

Analysis of mercury using a gold film detector

ATOMIC ABSORPTION (AA) flameless spectrophotometry is currently the most commonly used method for the determination of mercury in liquid matrices. However, serious limitations of the technique, including inconsistencies in the liquid calibration standard, interferences, and poor reproducibility, have raised questions regarding the accuracy of the AA method. The thin gold film (gf) technique described in this paper overcomes these limitations and at the same time reduces the complexity of mercury analysis.

The detection of elemental mercury vapor by thin gf sensors is a technique developed and patented by the Jerome Instrument Corporation.[1] The adsorption of elemental mercury vapor on a gold film approximately 200 Å in thickness produces a pronounced resistance change in the film; this resistance change is linear in the range of 1–100 ng of mercury.[2]

Dedicated, portable instruments utilizing the thin gf sensor for the analysis of mercury in dry soils by direct combustion and in air by direct sampling have been in use for several years. Recently a thin gf mercury analyzer and sample delivery system, the Jerome Instrument model 511, has been designed for the analysis of mercury in liquid matrices.

Mercury vapor, released in an air stream from aqueous solutions using wet-chemical procedures described later, is drawn into the instrument by an internal pump. The elemental mercury passes over, and is adsorbed and integrated by, the thin gf sensor. This integrated electronic signal is converted by a microprocessor to the mass of mercury per unit volume of sample. Data presentation by direct digital readout is in nanograms of mercury. Saturation of the sensor occurs after 500 ng of mercury has been accumulated; full sensitivity is reestablished in 10 min by thermal desorption of the mercury from the sensor.

Mercury concentrations normally found in liquid matrices such as water, urine, and blood are in the low nanograms per milliliter range. But quantitative analysis depends on a system that is not only sensitive to mercury, but is also selective for the element. A serious limitation to the AA technique for mercury analysis is the presence of interfering substances such as H_2O, SO_2, O_3, and a variety of organic and inorganic compounds.[1–6] The complexity of the techniques developed for the preparation and analysis of liquid samples for mercury are a result of the efforts to overcome these interferences.

The thin gf sensor's specificity for mercury eliminates most interferences common to the AA technique,[7,8] and its design has resulted in significant improvements in signal reproducibility, calibration technique, and full-range linear response. The glassware system for sample preparation and delivery eliminates potential mercury loss from the sample. Microprocessor control reduces the complexity of the instrument's operation to a single manual control. With a minimum detection limit of 1.0 ng of mercury, the volume of sample necessary for analysis is usually less than 5 mL. Thus, the amount of reagent used in sample preparation is significantly reduced, minimizing the reagent blank. The system is field portable for on-site analysis where degradation of the sample due to transportation and long storage is a concern.[8]

Calibration

The thin gf technique determines the mass of mercury per unit volume of sample; thus, calibration can be performed using the most basic standard possible—the vapor pressure of mercury.[9] A small drop of liquid mercury in a closed container, e.g., a 300-mL polyethylene bottle, will saturate the enclosed air at a value which depends only on temperature. The effect of total pressure on the vapor pressure of mercury is negligible. The relationship of mercury concentration in ng/cm^3 to temperature is shown in *Table 1*.

With the saturated mercury vapor maintained at a constant temperature, a known mass of elemental mercury is injected directly into the flow path of the thin gf sensor using a gas-tight syringe. The ana-

lyzer responds linearly to a series of mercury vapor standards. After a 10-min film heat which thermally desorbs the accumulated mercury, sensitivity and full range linearity are restored. This is illustrated in *Figure 1*.

Figure 2 shows the excellent correlation that exists between the vapor phase and aqueous mercury standards. However, the correlation will suffer due to the instability of liquid standards and the errors that occur in the preparation of the stock and working liquid solutions.

An accurate vapor standard depends on maintenance of the calibration vessel at a constant temperature and withdrawal of a precise volume of the standard. Dilution is not necessary since the vapor standard is within the working range of the instrument. Oxidation of the mercury droplet, which could reduce the vapor pressure of mercury, is prevented by periodic light shaking of the calibration vessel.

However, liquid standards for mercury, both stock and working solutions, have shown varying degrees of instability. For example, a 1000-ppm ± 1% mercury reference solution (certified AA standard), with an expiration date sixteen months from the date of initial use, over a period of four months decreased in mercury concentration by more than 20%. Working solutions of 20 ppb prepared from a liquid standard according to well-documented procedures will, when shaken slightly, evolve elemental mercury in significant quantities in the head space

above the solution. As a result, the linear correlation that is observed for the vapor versus aqueous standards immediately after preparation of the working solution can deteriorate significantly over several hours.

Mercury reference standards for mercury in solution are prepared by weighing out and dissolving crystals of $HgCl_2$ in distilled water that has been slightly acidified. The significant sources of error in this technique are the weighing of the $HgCl_2$, the purity of the $HgCl_2$, and the possible mercury contamination of the labware used. The solution is then subject to decomposition as noted previously.

Whether the reference standard is purchased in liquid form or prepared by dissolving $HgCl_2$ in distilled water, concentrated stock solution must be diluted from one million ng/mL to a working solution containing 20 to 100 ng/mL. Possible sources of error include the dilution process itself, and the possibility exists for mercury contamination or the loss of mercury to the glassware used in the dilution process.

Inteferences

Independent studies regarding the lack of response of the thin gf sensors to interferences common to AA have been published,[6,7] and some of the results are shown in *Table 2*. Murphy[6] considers the chemicals listed in Table 2 to be some typical examples of the troublesome types of samples that cause interference in the direct determination of mercury. The gold film system permits each of these samples to be analyzed directly and accurately without interferences from possible gaseous emissions that may be interpreted as mercury.

SO_2, ozone, organic and inorganic compounds, and fine particulates do not cause a response of the thin gf sensor; the gf sensor also does not respond to water vapor. As a result, drying agents such as magnesium perchlorate, which have been shown to be a negative interference with AA instruments, are not necessary with the gold film detector.[4]

Also noteworthy is that several wet chemical preparations include two or three additional reagents to eliminate potential AA interferences such as sulfides and chlorine. The lack of response by the gf method to these interferences can thus simplify the chemical preparation of a sample.

Reproducibility, precision, and accuracy

In AA analysis, reproducibility is dependent on the rate at which mercury is liberated from solution. Factors which affect this rate of release are pump rate, bubbler characteristics, sample matrix, sample volume, and relative strength of the reducing agent.[10,11]

In contrast, the integration of the mercury signal by the thin gf sensor makes the analyzer relatively independent of the factors which affect the rate of release.

The precision of the analyzer was demonstrated in an independent evaluation comparing the model 511 to a flameless AA spectrophotometer.[12] Forty-five urine samples were analyzed in triplicate with each instrument. The sample size analyzed by the gold film detector was 0.2 mL, as compared to a 2.0-mL sample required by the AA spectrophotometer. The results listed in *Table 3* gave a coefficient of correlation of 0.985 between the two instruments. The relative standard deviation of the results

obtained with the gold film detector was 2.4%, as compared to 6.8% for the AA instrument.

As mentioned previously, the linear range of the gold film detector is 1 to 100 ng with gf saturation occurring at 500 ng. At levels above 100 ng, the microprocessor automatically corrects for nonlinear response. A series of 2-mL injections of mercury-saturated vapor gave responses of between 21 and 26 ng, totaling 470 ng, 94% of film saturation. The vapor reference was maintained at 18.5°C. The RSD for this set of data was 5.7%.

Suggested analytical procedure for mercury in solution

Gold film technology coupled with microprocessor control and an improved glassware delivery system have enhanced the quantitative analysis of mercury in liquid matrices, while at the same time reducing its complexity.

An illustration of this is the recommended procedure for the preparation and subsequent analysis of mercury in urine. The sample preparation is a modification of the American Congress of Government Industrial Hygienists (ACGIH) method No. 165, published in the ACGIH *Analytical Methods Manual*.

It is extremely important to immerse new glassware in concentrated HNO_3 for at least 8 hr. After this initial mercury decontamination, normal rinsing in acid is required to ensure mercury-free glassware. To prevent contamination of the stored glassware, continuous immersion in distilled water is recommended.

It is important that the sample preparation glassware *never* come into contact with reducing agents such as stannous chloride or sodium borohydride, because mercury in the sample can be lost due to carry-over of these reagents.

The detailed procedure is as follows: Under a fume-hood, add 1 mL of concentrated HNO_3 to a 30-mL Pyrex test tube. Pipet 0.25 mL of a urine sample into the test tube; allow 5 min for the digestion of the sample at room temperature. Add enough distilled water to bring the final volume to approximately 30 mL; the final volume is not critical.

Transfer the diluted sample to the reaction vessel. Attach the vessel to the bubbler. Inject 0.5 mL of 10% stannous chloride solution into the reaction vessel. This closed system eliminates the possibility of mercury loss from the sample to the atmosphere.

Immediately press SAMPLE START—the system automatically rezeroes and aeration commences. The 60-sec cycle will automatically go to completion, and the mercury value will be displayed in nanograms with the reading held until the next sample cycle. Data can also be displayed on a chart recorder or entered into a computer.

Forty urine specimens with an average mercury concentration of 50 μg/L can be analyzed before film saturation occurs.

Summary

The incorporation of thin gf sensors into an analytical system designed for the determination of total mercury in an aqueous matrix represents a distinct improvement over the AA method. The integrating characteristics and the selectivity of the gf sensor to a mercury signal are the major reasons for this improvement.

Determination of Nanogram Quantities of Mercury in Liquid Matrices by a Gold Film Mercury Detector

P. J. Murphy

Industrial Laboratory, Kodak Park Division, Eastman Kodak Company, Rochester, New York 14650

Many papers have been published in recent years dealing with mercury analysis. One of the most significant mercury methods was developed by Hatch and Ott (*1*), who reported that mercury could be directly reduced to the elemental state in an aqueous medium and the mercury vapor measured by atomic absorption spectrometry. Another important technique was developed by Anderson (*2*), who demonstrated that mercury could be collected on gold for subsequent determination by atomic absorption. McNerney (*3*) and Ohkawa (*4*) have taken advantage of the amalgamation properties of mercury and gold and utilized a sophisticated instrument based on a change in the resistivity of a gold film detector. However, while this instrument has improved sensitivity (*4*) and analytical versatility, the technology developed using this important nonatomic absorption technique was limited to air samples or those samples decomposed by combustion.

It is the purpose of this paper to describe the use of a gold-film mercury detector coupled with a direct reduction technique to determine mercury in aqueous media. The system allows analysis of a wide variety of samples while eliminating most of the interferences usually associated with cold vapor atomic absorption techniques.

EXPERIMENTAL

The instruments used in this study were a Gold Film Mercury Detector, Jerome Instrument Corporation, and a Coleman MAS-50, Coleman Instruments. Additional equipment included Coleman MAS-50 aerators and Standard 500-mL BOD bottles.

Two reducing agents were employed: tin(II) chloride solution (10% in 10% HCl) and sodium borohydride solution (0.2% in 40% NaOH). The standard solution used was prepared using reagent-grade mercury sulfate.

All other chemicals used were reagent-grade and "mercury-free" and included acetone, sodium sulfite, sodium thiosulfate, pyridine, ammonium hydroxide, hydrochloric, nitric, and sulfuric acids.

RESULTS AND DISCUSSION

Figure 1 shows the adaptation of a gold film mercury detector set up to monitor mercury in aqueous solutions. In this system, mercury vapor is volatilized from solution onto the gold collector coil by means of a suitable reducing agent. The collected mercury is then thermally volatilized and collected on the gold films located internally in the instrument. Mercury adsorption onto these films causes an increase in resistance (displayed on the digital galvanometer) and that increase is proportional to mercury content. The instrument is calibrated after each determination using standard addition techniques.

Since the proposed system involves quantitative collection of the volatilized mercury, a time study was needed to determine the optimum collection conditions. Table I shows that 2 min are necessary to complete the collection cycle. The remainder of the data were obtained using the 2-min collection cycle, which begins after introduction of the reducing agent.

Table II shows comparative data of the proposed system and a conventional cold vapor atomic absorption analyzer. The different sample preparations included: Group 1, direct dissolution in water; Group 2, wet digestion with nitric and sulfuric acids; Group 3, direct dissolution in water plus addition of hydroxide (since acidification of sodium thiocyanate with nitric acid is potentially hazardous, hydroxide is added before the addition of the reducing agent. Hydroxide effectively competes with thiocyanate and allows for direct reduction of the mercury); Group 4, use of 0.2% sodium borohydride solution as the reducing agent (mercury forms a strong complex with iodide (HgI_4^{2-}) which keeps the mercury from becoming completely reduced on the acid side with tin(II)

chloride. Therefore, it is desirable to use a stronger reducing agent such as sodium borohydride in alkaline medium to quantitatively produce atomic mercury. All other data in this paper were obtained utilizing tin(II) chloride as the reducing agent); Group 5, addition of nitric acid followed by boiling (nitric acid addition and boiling allows for degradation of any organic mercury to the ionic state. It also might be noted that the proposed system allows for mercury analysis in water samples at the nanogram per liter level); and Group 6, precipitation of silver with a potassium bromide solution (5). There were no significant differences between the results obtained by the analyzers (correlation coefficient, r_{xy} = 0.9995), except that the gold film system offers lower detection levels (see Groups 1, 3, and 6, Table II).

The chemicals in Table III represent an interference study to show the advantages of the proposed system over cold vapor atomic absorption. Each chemical was dissolved in distilled water and diluted to 100 mL to give the indicated percentage by weight. Mercury and tin(II) chloride were added to the diverse matrices and the element was monitored by both techniques. In each case, erroneously high values were obtained using cold vapor atomic absorption. Gaseous vapors, such as sulfur dioxide and ammonia, which absorb at the 253.7-nm wavelength, showed positive interference. The chemicals listed in Table III are some typical examples of the troublesome types of samples that cause interference in the direct determination of mercury. The attractive feature of the gold film system is that each of these samples can be analyzed directly and accurately without interference from possible gaseous emissions that may be misinterpreted as mercury.

Quantitative Analysis of Mercury Vapor by Gold Film Sensors

by Richard T. McNerney

JEROME INSTRUMENT CORPORATION

PRESENTED AT THE 1983 MEETING OF THE
AMERICAN INDUSTRIAL HYGIENE ASSOCIATION
PHILADELPHIA, PA

The detection of elemental mercury vapor by a thin Gold Film sensor was developed and patented (U.S. Patent #3,714,562) by J. McNerney, founder of the Jerome Instrument Corporation. (Figure 1)

The sensor, produced by high vacuum deposition onto a ceramic substrate, undergoes an increase in electrical resistance proportional to the mass of mercury in a sample. Two films, a reference and a sensor, are placed in opposite arms of a Wheatstone Bridge, a sensitive electrical circuit capable of detecting small changes in resistance. (Figure 2) Since mercury vapor is unique in its ability to alter the resistance of the Gold Films, interferences common to atomic absorption (AA) instruments, i.e. water vapor, SO_2, organic vapors, and particulates, are eliminated.

The Model #411 Gold Film Mercury Vapor Analyzer, designed for the analysis of mercury vapor in the workplace environment, incorporates a pump and digital display with microprocessor control. (Figure 3) Activating either the 10 second sample or 1 second survey mode starts an internal pump which draws a precise volume of air over the Gold Film sensor. The microprocessor computes the concentration of mercury, displaying the results on an LCD meter. This reading remains displayed until the next sample cycle is activated at which point the microprocessor automatically resetes the meter.

The microprocessor will ensure a linear response until the Gold Film has absorbed approximately 500 nanograms of mercury. (Figure 4) As mercury accumulates on the sensor, the percentage of saturation is indicated by pressing the Sensor Status button. Approximately forty 10 second or 400 1 second samples can be taken in atmospheres containing 0.1 mg of Hg/m³ (current OSHA TLV) before saturation reaches 100% (500 ng). At that point, a 10 minute film heat cycle is activated to desorb the accumulated mercury from the sensor and return it to its original baseline resistance. (Figure 1)

CALIBRATION

The Gold Film technique determines the mass of mercury per unit volume of sample. Thus, calibration of the Model #411 can be performed simply and directly by using the most basic standard possible: the vapor pressure of mercury.

A small drop of liquid mercury in a closed container, e.g. a 300 ml polyethylene or thermos bottle, will saturate the enclosed air at a value which depends only on temperature. (Figure 5)

The concentration of mercury is calculated by utilizing relationships of pressure, temperature and volume as expressed in the Ideal Gas Law. It should be noted that the concentration is not dependent on atmospheric pressure (P_A) but the vapor pressure of mercury (P_{Hg}) and the measured temperature of air saturated with mercury (T_m). (Figures 6 & 7)

With the calibration vessel maintained at a constant temperature, a known mass of mercury saturated vapor is injected directly into the flow path of the Gold Film sensor of the Model #411 using a gas-tight syringe.

Referring to Figure 8, 1.12 ng of mercury is introduced into the Model #411 using this procedure and activating the 10 second sample cycle. With the pump rate set at 0.75 L/min (12.5 cc/sec), the 1.12 ng of injected mercury will be diluted with 125 cc (12.5 cc/sec X 10 sec) of "Mercury free" air. This is equivalent to a mercury vapor concentration of 0.106 ng/cc (1.12 ng/125 cc)*. The digital meter response of the Model #411 is adjusted electronically to reflect this concentration. The linear response of the Model #411 (Figure 10) through its full operational range allows a single point calibration.

PRECISION & LINEARITY OF THE MODEL #411

The integrating characteristics of the Gold Film sensor, together with microprocessor-control, ensure excellent reproducibility and linear response.

Figure 9 represents a series of repetitive 10-second samples taken by the Model #411 in an atmosphere with a mercury concentration of 0.129 mg/m^3. Sampling was initiated with "Mercury-free" Gold Film sensors and concluded when sensor status indicated 60% saturation. The standard deviation and precision for this set of data is 2.44 and 2%, respectively.

Similarly, the Model #411 sampled atmospheres containing mercury concentrations ranging from 0.010 to 0.375 mg/m^3. Sampling was initiated with a "Mercury-free" Gold Film sensor and concluded when the sensor status indicated 30% saturation. The graph in Figure 10 illustrates the direct correlation between the meter response of the #411 and the known mercury concentration.

INTRODUCTION

Molybdenum does not commonly occur in mine-mill effluents. It is also an element of little or no environmental concern. Despite years of investigation AMAX, INC., the largest producer of molybdenum in the world, and the U.S. EPA as well as the state of Colorado, have yet to find a case where molybdenum has been responsible for environmental damage. Excessive molybdenum in livestock water supplies can, however, give the trots to cattle. Why then should molybdenum be removed from water?

First, if there is enough of it, molybdenum removed from effluents may one day represent a profitable resource although that is not the case at current prices. Second, regulatory limits have been promulgated in some states, apparently motivated by the attitude of some regulators that everything should be regulated on principle, and molybdenum should have to be removed to meet some arbitrary standard "In case there are environmental effects

that are not yet known." One can always hope that a new trend toward more pragmatic regulatory attitudes may one day dawn.

OCCURRENCE OF MOLYBDENUM IN THE MINE-MILL ENVIRONMENT

Molybdenum is mined as a primary product as molybdenite MoS_2 in several porphyry deposits in the western U.S.A. and Canada. It also occurs as a by-product of copper mines in the U.S.A., Canada, and several South American countries, notably Chile and Peru.

Molybdenum also occurs in volcanic formations associated with and/or overlying primary uranium deposits in the southwestern U.S.A. and is sometimes associated with other minerals (e.g., uranium, tungsten and gold) in breccia pipe deposits scattered throughout the western U.S.A.

In the mining and milling of primary molybdenum deposits, e.g., at Climax, Henderson, Colorado, etc., residual particles of MoS_2 in the tailings may oxidize with time to release small concentrations of molybdenum to the seepage water and tailings decant solutions. Drainage from wasterock dumps may also contain some molybdenum. Molybdenum in minewater and tailings seepage and decant water from the Climax Mine was described by GOTT and LAFFERTY (1978) and by RAMADORAI (1978).

In uranium ore milling, molybdenum can build up in process solutions or occur in mine drainage.

At in situ leach test projects for uranium recovery from deep deposits in New Mexico, molybdenum was identified in the leach liquor that was pumped from the wellfield and represented a potential metallurgical interference in the ion exchange uranium recovery process.

Molybdenum also occurs associated with the gold ores recently discovered in the major Hemlo gold district and is expected to range between 0.5-3.0 mg/l in wastewater from this operation before being treated and below 1.0 mg/l in the discharged effluent.

The PEDCO (1983) report provides an interesting insight into approximate ranges of molybdenum levels in mine-mill effluents. In the case of some mine categories, e.g., taconite, phosphate, etc., molybdenum was not considered important enough to be included in the investigation. On the other hand, elevated molybdenum levels in effluents, process water, and leachates were observed for molybdenum, copper, and gold-silver recovery operations. A question arises as to whether molybdenum may possibly be a pathfinder element for gold mineralization in volcanic environments.

Molybdenum was generally found in the PEDCO (1983) investigation to occur in mill tailings decant solutions, minewater, and leachates of tailings solids, wasterock, and ore in a range of 0.002-2 ppm but averaging less than 0.5 ppm. Examples of industry classes where molybdenum exceeded 1 ppm are considered unusual except in some uranium, molybdenum, copper, and gold districts:

SUMMARY OF PEDCO (1983) DATA

	Average (ppm)	Number of Samples	Maximum (ppm)
NEW MEXICO URANIUM DISTRICT			
Surface Mine Waste and Leachate	LT 0.01	4	LT 0.01
Surface Mine Waste Water Leachate	0.02	4	0.034
Minewater Pond Liquid	0.436	5	0.76

Lowgrade Ore Water Leachate	1.09	2	1.25
NEVADA GOLD-SILVER DISTRIC			
Tailings Pond Liquid	0.32	2	0.51

A granular activated alumina is used for fluoride adsorption. The material is a by-product of aluminum production. It is primarily an aluminum oxide which has been activated by exposure to high temperature and caustic soda. The material is highly porous, and the surface area per unit of weight is quite high.

RUBEL (1984) recommends the use of 28-48 mesh Alcoa F-1 grade alumina in defluoridation processes.

CAPACITY OF ACTIVATED ALUMINA FOR F^- REMOVAL

Capacity of activated alumina for F^- removal is very pH dependent as demonstrated by WU (1978) who first suggested that activated alumina capacity for fluoride uptake from water is much greater at pH 5.5 than at 7.0. He reported maximum removals of 4,200 grains/ft^3 at pH 5 with pure NaF solutions. Other investigatiors who have made bench, pilot, or commercial installation studies have reported much lower capacities because they have not understood or chosen to operate at optimum pH conditions.

RUBEL (1984) cites three plants which have operated routinely for years at a low cost meeting the municipal fluoride levels. These are listed below. By paying close attention to pH control, the three plants are able to routinely remove in excess of 2,000 grains/ft^3 (4,600 g/m^3). For higher fluoride concentrations, the activated alumina adsorption capacity increases. For a water with 22 mg/l F^-, the alumina capacity reaches 4,500 grains/ft^3 (10,400 g/m^3).

In this optimum pH range (5.0-6.0), other ions that compete with fluoride for the same adsorption sites are not adsorbed. Included are silica, which is adsorbed in the pH range 6-10, and some hardness ions which are removed in the pH range 7 through 10. Hardness removal occurs at the start of a treatment run. However, activated alumina preferentially adsorbs fluoride; therefore, as the run progresses, hardness removal ceases. At the optimum fluoride removal pH, some organic molecules and some trace heavy metal ions are also adsorbed. However, except for arsenic, these are completely regenerated along with the fluoride. Arsenic presents a problem as it is preferentially adsorbed over fluoride by the alumina at the same optimum pH. Arsenic is more difficult to regenerate than fluoride. Therefore, when excess fluoride and arsenic are present in a water supply, a special treatment technique is required as described by RUBEL and WOOSLEY (1978).

EXAMPLES OF PLANTS USING Al_2O_3 ADSORPTION OF F^-

	Startup Year	U.S. gpm	m^3/d
Lake Tamarisk, Desert Center, California	1970	1,100	6,000
Rincon Water Co., Vail, Arizona	1972	500	2,700
Town of Gila Bend, Arizona	1978	900	4,900
Roolberg Tin Mine, Transvaal	1985	95	518

CONCEPTUAL DESIGN

Of the many configurations to choose from, i.e, gravity or pressure flow, single or multiple treatment beds, upflow or downflow treatment flow direction, and series or parallel treatment vessel arrangement, RUBEL (1984) reports that the most efficient, cost effective configuration is a parallel downflow multiple bed pressure system. Best cost effectiveness is achieved (for both capital and operating costs) with two treatment beds.

The two-bed series combination yields the highest fluoride loading on the media, and the lowest fluoride level in the treated water, but this is often too low to be desirable. The parallel system allows an opportunity to blend two streams.

REGENERATION OF ALUMINA

Alumina is regenerated using a 1% sodium hydroxide solution. Optimally, 50 percent NaOH solution is used which may require heating as it freezes at 55°F and is very viscous below 70°F. Fluoride ions are repelled from the alumina granules when the pH rises above 10.5.

0.4 gallons (5 lbs.) of 50% NaOH solution is required per ft^3 per regeneration. The caustic requirement for regeneration is a function of the raw water fluoride level which dictates the frequency of regeneration and the volume of water over which the cost must be distributed.

Use of too highly concentrated NaOH solution enhances comsumption of alumina granules.

MEDIA CONSUMPTION

Consumption of alumina should be close to zero in a well-operated activated alumina fluoride water treatment plant. Excessively long backwash periods cause excessive

alumina losses through attrition and elutriation. Monitoring of backwash fluids can help detect this.

During regeneration, excessively high and/or low pH exposure attacks the media. If the regeneration solution exceeds 1.5% NaOH, the solution is aggressive to activated alumina.

Also, if the pH of the post regeneration neutralizing solution (acid addition) is below pH 2.0, the alumina dissolves very rapidly with resulting losses.

Finally, alumina can be lost through the effluent underdrain collection system within the bed. If alumina grains ever appear in the treated effluent, this indicates that the collection system is in need of repair.

A conservative bed replacement estimate according to RUBEL (1984) is ten percent per year.

OPERATING SEQUENCE

1. Feed pH adjustment to Ph 5.0-6.0.
2. Adsorption mode - downflow.
3. Backwash mode.
4. Regeneration.
5. Neutralization after regeneration.

Raw water is used in each of these steps.

Details of the operation of an activated alumina plant for defluoridation are provided by RUBEL (1984) including several knowhow items which would prove helpful in optimizing results for a given plant.

Fines that accumulate on top of the alumina bed should be removed to avoid an unnecessarily high pressure drop across the bed when commencing a run.

BACKWASHING

Backwashing of the bed with raw water after each run prior to regeneration is important to remove suspended solids filtered from the feedwater. Upflow backwash expands the bed. Backwash at 8-9 gpm/ft^3 expands the bed about 50%, which is recommended. Normally, backwashing lasts ten minutes. RUBEL (1984) provides a valve operation chart for the backflush mode.

REGENERATION

Regeneration of the bed on completion of an adsorption run generally includes two discrete regeneration steps. First is upflow regeneration following draining of the bed after backflushing. Regeneration is followed by an upflow rinse. The unit is then drained to the top of the bed prior to the second regeneration step which is downflow. Both steps use 1% (by weight) NaOH solution.

A skilled operator can reduce the concentration of NaOH to 0.75% and achieve the same high regeneration efficiency; however, below 0.75%, the efficiency drops rapidly. At this lower caustic concentration, the saving in NaOH consumption amounts to 20%.

As a rule of thumb, fifteen gallons of 1% NaOH solution is needed per cubic foot of treatment media. The minimum time for the regenerant solution to flow through the bed is thirty minutes. Thirty-five minutes is recommended for a 5' bed. A flow of 2.5 gpm/ft^2 for thirty-five minutes per regeneration is usually sufficient, which equates to 0.2 gallons of 50% NaOH per cubic foot of treatment media for each regeneration step (upflow and downflow).

After backflush, prior to upflow regeneration, the bed must be drained to remove water which dilutes the caustic concentration. Upon completion of draining, the upflow regeneration starts. On completion of the upflow regeneration, the caustic feed pump is turned off and the day tank refilled. Raw water continues to flow for sixty minutes at 2.5 gpm/ft^2 upward through the bed to flush out the fluoride. After this rinse step is completed, the vessel is drained to the top of the treatment bed, again to remove dilution water. Then, downflow regeneration is followed by a draining period prior to the start of the neutralization mode.

NEUTRALIZATION

Neutralization is critical to the success of the following adsorption (treatment) run. The objective of this mode is to return the bed to the treatment mode as rapidly as possible without dissolving the activated alumina. The pH of the alumina upon completion of regeneration is 12 plus. It must be adjusted down to 5.5. Therefore, it must pass through pH ranges where ions that compete for adsorption sites on the alumina will be loaded into the bed. The minimum pH that can safely be reached is pH 2.5. A lower pH is too aggressive and is not recommended.

After 15 minutes of downflow regeneration, the flow is adjusted to the normal treatment mode rate. The acid pump is started, and the pH of the raw water adjusted to 2.5. Acid feed rate again varies with the alkalinity of the raw water. The raw water flow rate may have to be reduced to achieve pH 2.5 at the maximum acid pump feed rate.

As the neutralization mode proceeds, pH of the treated water gradually drops below 12. The rate of pH reduction increases at an increasing rate. As the treated water drops below ten, the treated water fluoride level begins to drop below that of the raw water. At that time, treatment begins. At the point where the fluoride level drops below the MCL, the water becomes usable and can be directed to storage even if the pH is still high (say pH 9.5).

When the treated water pH drops to 8.5, the raw water pH is adjusted up to 4.0 as the bed rapidly neutralizes. When the treated water drops to pH 6.5, the raw water is adjusted up to pH 5.5 where it remains through the duration of the run.

Volume of wastewater produced during the regeneration of the alumina bed varies with the physical and chemical characteristics of the raw water. A useful rule of thumb is 300 U.S. gallons per ft^3 of media, i.e., 40 m^3 wastewater per m^3 media per regeneration.

Typical volumes of wastewater generated during each regeneration cycle for a hypothetical plant as described by RUBEL (1984) are:

Backwash	60 U.S. Gal.
Upflow Regeneration	15 U.S. Gal.
Upflow Rinse	30 U.S. Gal.
Downflow Regeneration	15 U.S. Gal.
Neutralization	180 U.S. Gal.
TOTAL	300 U.S. Gal.

Operating experience for each given plant will soon come up with deviations from these quantities.

DISPOSING OF WASTEWATER

All the known fluoride treatment plants using activated alumina are located in areas with net evaporation climates and, as such, are suitable for disposal of the regeneration wastewater containing flouride into lined evaporation ponds.

LABORATORY REQUIREMENTS

RUBEL (1984) recommends that the operator of an activated alumina fluoride removal plant be equipped with the operations and maintenance (O&M) manual for the plant and also the latest edition of Standard Methods for the Examination of Water and Wastewater by AWWA-APHA and basic laboratory equipment. Primary analytical needs are to determine pH and fluoride. Fluoride measurement can be by ion-specific electrodes provided the

:t buffer (TISAB) is employed for the water to be treated. There are also two te wet chemistry methods using SPADNS and Alizarin. Distillation and/or correction terferring ions (e.g., alkalinity, aluminum, iron, sulfate, etc.) are required for te results.

,TING COSTS FOR DEFLUORIDATION BY ACTIVATED ALUMINA

include the following:

- Treatment chemicals.
- Operator labor costs.
- Utility costs.
- Replacement alumina.
- Replacement parts and miscellaneous materials.

L (1984) discusses each cost item in some detail.

ding to RUBEL (1984), the U.S. price for ALCOA F-1 28-48 mesh activated alumina s from $0.697/lb to $0.516/lb depending on quantity.

ıting costs (1984) vary as follows:

Operating Cost Items		U.S. Dollars per 1,000 U.S. Gallons Min. $	Max. $	U.S. Treated Ave.
Treatment Chemical -	Acid	0.02	0.08	0.05
	Caustic	0.02	0.12	0.05
Operating Labor		0.03	0.10	0.06
Utilities		0.005	0.05	0.01
Replacement Media		0.005	0.03	0.02
Replacement Parts, Etc.		0.05	0.10	0.01
TOTAL		0.085	0.39	0.20

FLUORIDE

	$/m³ Min. $	Treated Water Max. $	Ave. $
Treatment Chemicals - Acid	0.005	0.020	0.013
Caustic	0.005	0.030	0.013
Operating Labor	0.008	0.030	0.016
Utilities	0.001	0.013	0.003
Replacement Media	0.001	0.008	0.005
Replacements Parts, Etc.	0.013	0.026	0.003
TOTAL	0.033	0.127	0.053

CAPITAL COST FOR ACTIVATED ALUMINA DEFLUORIDATION PLANT

RUBEL (1984) estimated costs for a 600 U.S. gpm (3300 m³/d) defluoridation plant in a warm Arizona climate at $347,000 of which $138,000 was for the lined wastewater evaporation pond. The cost breakdown was as follows:

Flowrate: 600 U.S. gpm, 3300 m³/d.

Process Equipment	
Treatment Vessels	$ 33,000
Treatment Media - Alumina	20,500
Process Piping, Valves, and Accessories	16,400
Instruments and Controls	8,300
Chemical Storage Tanks	21,000
Chemical Pumps, Piping and Accessories	6,300
Subtotal	$105,000
Process Equipment Installation	
Mechanical	$ 36,000
Electrical	7,000
Painting and Miscellaneous	4,500
Subtotal	$ 47,500
Miscellaneous Installed Items	
Wastewater Evaporation Pond - Lined	$138,000
Building and Concrete	28,000
Sitework, Fence, and Miscellaneous	11,000
Subtotal	$177,000
Contingency 4%	17,000
TOTAL	$347,000

The Removal of Excess Fluoride From Drinking Water by Activated Alumina

Frederick Rubel Jr. and R. Dale Woosley

Described here are cost-effective operating practices developed at three water treatment plants for removing excess fluoride from drinking water by activated alumina. By use of these methods the fluoride removal capacity of alumina was increased by a factor of five.

Under the national Interim Primary Drinking Water Regulations maximum contaminant levels (MCL) in potable water supplies have been established for ten inorganic chemicals, including fluoride. The MCL for fluoride varies from 1.4 to 2.4 mg/L, depending upon the annual average of the maximum daily air temperatures (Table 1). If the prescribed maximum level is to be enforced, its achievement must be technically and economically feasible.

Since it became known that excess fluoride in drinking water caused mottled teeth in children,[1] many methods of removing fluoride have been developed. One of them employs activated alumina to defluoridate water supplies. Although many investigators have found that activated alumina is quite effective in reducing fluoride to very low levels in treated water, there is an abundance of confusion as to the useful capacity of activated alumina.

Churchill,[2] in his 1936 patent on the use of activated alumina for fluoride removal, states that a pH of 5 to 6.5 should be used during treatment for best results. There is no stated capacity in his patent. E.A. Savinelli and A.R. Black,[3] in their 1958 bench experiments, showed that a capacity of 7800 g/m³ (3400 grains/cu ft) was achieved when treated water pH was 5.6. Their studies were made with tap water to which sodium fluoride had been added. Yeun C. Wu,[4] in a recent article, again shows that treatment pH is quite important for high removal capacities. He reports maximum removals of 9600 g/m³ (4200 grains/cu ft) with treatment at pH 5.0 in pure sodium fluoride solutions. Other investigators[5,6] who have made bench, pilot, or commercial installation studies report much lower capacities because they have not understood or chosen to operate at optimum pH conditions.

Two plants that have had several years of low-cost experience in producing waters with fluoride concentrations reduced to acceptable levels are the Lake Tamarisk plant at Desert Center, Calif., with nine years of operation, and the Rincon Water Co. plant at Vail, Ariz., with six years of operation. A third plant began operation in Gila Bend, Ariz., in May 1978. By paying close attention to pH control, the three plants are able to operate routinely with removal capacities exceeding 4600 g/m³ (2000 grains/cu ft). Removal capacities exceeding 7000 g/m³ (3300 grains/cu ft) were observed during the pilot work done at Gila Bend, Ariz., to confirm that the developed operating practices would work on that water supply.

Development work with pilot-plant equipment on a continuing basis has perfected the water treatment and alumina regeneration processes at each of these locations. This article outlines the operating practices developed for removing fluoride to acceptable levels.

Fluoride Removal Technology

This article is based on pilot-plant experiments and plant data for which granular activated alumina* (mesh size 28 to 48) was used.

The basic principles of fluoride removal technology are

1. Optimizing the environment for sorbing of fluoride ions to activated alumina surfaces
2. Preventing competing ions from occupying alumina surfaces that should be reserved for fluoride ions
3. Upon regeneration of an expended treatment bed, taking all steps necessary to remove all fluoride ions from the bed before returning it to treatment.

There are also many "common sense" principles that apply to the process which, though important, are not as critical as the three listed.

There are four modes of operation: treatment, backwash, regeneration, and neutralization. Operating details for each mode are discussed here.

Treatment mode for virgin or regenerated treatment bed. The optimum environment for fluoride removal exists when raw water pH is adjusted to 5.0–6.0 by sulfuric acid injection. Because acid feed rates are a function of the raw water alkalinity, they vary from one water to another. The best results obtained to date have occurred when the raw water pH has been held carefully at 5.5. In this environment the attraction of the fluoride ion to the activated alumina surface is most favorable and interference by competing ions is minimal. Adsorption is the most probable mechanism for fluoride ion removal from water, but because work in this area is still in progress, discussion of mechanism is premature. In applications

to date, treatment bed capacities consistently have exceeded 4600 g/m³ (2000 grains/cu ft), and some runs have exceeded 9200 g/m³ (4000 grains/cu ft).

As raw water pH moves above 6.0 or below 5.0, fluoride removal capacity deteriorates at an increasing rate. For example, from previous experiments it has been shown that at pH 7.0 bed capacity is about 1100 g/m³ (500 grains/cu ft). Though efficiency might appear to be the same, breakthrough occurs earlier and treatment runs are shorter. Fluoride removal efficiency at optimal pH approaches 100 percent, as indicated by treated water fluoride concentration well below 0.1 mg/L during portions of the treatment run at each installation. This efficiency is achieved in waters with different chemistries including varying fluoride levels (Table 2). Superficial residence time (flow time through the bed neglecting the volume of bed material) is also a limiting factor: a 5-min minimum is a practical limit for maximum removal efficiency. Best results occur with flow directed down through the bed. Care must be taken to prevent a wall effect or channeling.

The initial effluent pH is high, with no fluoride removal, as explained in the discussion on neutralization mode. After a short period both pH level and residual fluoride drop to acceptable levels. At that point usable water can be directed to storage or distribution. Fluoride level drops rapidly to a very low level and remains there until breakthrough begins, at which point it increases gradually until the treatment run is terminated.

Treated water pH drops below 6. Because water of this pH is corrosive, the treated water pH must be adjusted to a desirable level (about 7.5) by injection of sodium hydroxide or by blending.

Backwash mode. For two reasons it is important that the bed be backwashed with raw water before each regeneration: first, any suspended solids that have been filtered from the raw water by the treatment bed tend to blind the bed and must be removed; second, even though filtration may not have taken place, the downward flow tends to pack the bed. Therefore, an upflow backwash expands the bed, breaking up any tendency toward wall effects or channeling. A backwash rate of 5–6 mm/s will expand the bed about 50 percent, which is adequate. Care must be taken to avoid backwashing granular bed material out of the treatment unit. Normally, backwash is completed within 10 min.

Regeneration mode. The object of regeneration is the removal of all fluoride ions from the bed before any part of the bed is returned to the treatment mode. The most successful regeneration is accomplished in two steps: the first is upflow immediately after backwash while the bed is still expanded, followed by an upflow rinse. The unit is then drained to the top of the treatment bed. The second regeneration step is downflow immediately followed by the neutralization mode. Regeneration steps employ 1 percent (by weight) sodium hydroxide solution flowing at a rate of 1.7 mm/s. With a standard treatment bed depth of 1.5 m, each regeneration step takes 35 min. Chemical consumption in each regeneration step is 27 L of 50 percent NaOH per cubic metre of treatment media (0.2 gal/cu ft). The intermediate upflow rinse flows at a rate of 3.4 mm/s for a period of 30 min. If the treatment bed depth varies from standard, flow rates and times must be adjusted. The regenerant solution is usually an in-line dilution of 50 percent sodium hydroxide with raw water, with the sodium hydroxide maintained at or above 21° C to prevent freezing. *

Neutralization mode. The object of this step is to return the bed to the treatment mode as rapidly as possible without dissolving the treatment media. As soon as the second (downflow) regeneration step has been completed, all of the fluoride should have been removed from the bed. At this point the bed is drained again to the top of the treatment media. Raw water with pH adjusted to 2.5 is then fed downflow at the normal treatment flow rate (Fig. 1). Sulfuric acid concentrations again vary with the alkalinity of the specific raw water. The entire bed has a pH range from 12.5 to 13.0, and as the top of the bed begins to

* this is ambiguous: 27 or (2x27 = 54L) ?

TABLE 5
Operating Costs At Existing Treatment Plants

neutralize and enter a treatment mode, the fluoride level in the treated water starts to drop below that of the raw water. Treated water pH also begins to drop. As the fluoride level drops below the mandatory limit, the water becomes usable and can be directed to storage or distribution. pH may still be high (9.0–9.5) in the treated water; however, this water can be blended with treated water of lower pH from other treatment units. When the pH is 9.0 to 9.5, the raw water pH is adjusted to 4.0 as the bed rapidly neutralizes. When the treated water pH drops to 7.5, the raw water pH is adjusted to 5.5, where it is maintained throughout the remainder of the run.

Initial Start-Up Procedures

When the bed material is first placed into the treatment unit, the vessel should be half filled with water. As the activated alumina is poured into the bed from above, the water dissipates the heat generated by the heat of wetting of the activated alumina, thereby preventing cementing of the bed. The water also aids in separating fines from the granular material; protects the underdrain assembly from impact; and initiates stratification of bed material. Once the bed is in place, it must be backwasned for an extended period until all of the alumina fines are flushed from the virgin bed. The flow is then reversed and downflow treatment begins for the virgin run.

Blending of Treated Water

Blending can take place in either large reservoirs or the treated water main. During a treatment run there is a long period when the fluoride level of the treated water is well below desired levels. As breakthrough occurs there is a long period of slowly increasing fluoride concentration in the treated water. It has been found that treated water can continue to flow to storage or distribution until the fluoride concentration reaches one and one half to two times the maximum allowable level; the resulting total average fluoride level continues to meet the prescribed fluoride level (one half the maximum allowable level).

When there is a large reservoir in which the major portion of a treatment run can be stored, blending takes place there. At locations where the reservoir is not large and there are two or more treatment units, staggered regenerations accomplish the same result; that is, a regenerated treatment unit will produce water of very low fluoride content while a second unit in the later stages of its treatment run may be producing water of a higher fluoride level. By mixing the effluent from the two units in the treated water main, an average fluoride concentration near the prescribed level can be maintained. Similarly, the treated water of high pH occurring early in the run for one unit can be blended with the low pH effluent of another unit in a later stage. The benefit of this blending is short-lived; soon the pH of the blended streams requires adjustment.

Disposal of Wastewater

The wastewaters resulting from backwash, regeneration, and the early part of neutralization are not suitable for consumption and must be discarded. The backwash water, which is only raw water, can be discharged to existing storm water disposal systems. The only objectionable feature of the regeneration waste is the high concentration of fluoride ions that cannot be returned to the groundwater aquifer. Its high pH can be neutralized. Disposal of waste of high fluoride concentration must comply with local wastewater discharge standards, which vary. Existing plants concentrate the waste in lined evaporation ponds; eventually the concentrated waste must be transferred to an acceptable disposal site or the fluoride must be reclaimed.

The volume of wastewater is approximately 4 percent of the total throughput.

Materials of Construction

The cost of a treatment plant is a function of the quality of the construction materials in its design. Trouble-free, low-cost plant operation can be achieved only by proper selection of materials to meet the service requirements of the process. Without considering the materials for concentrated acid and caustic

Treatment Units at Gila Bend, Ariz.

Treatment Plant at Gila Bend, Ariz.

Lake Tamarisk Treatment Plant at Desert Center, Calif.

Rincon Treatment Unit. Acid Line in Foreground

systems, treatment system materials must be suitable for service under the following conditions: (1) potable water system; (2) ambient temperatures (provision for thermal expansion); (3) exposure to sunlight (or protected); (4) pH 2-13; and (5) ease of maintenance (remove and replace with minimum logistics). Materials for the chemical storage and handling systems should comply with chemical manufacturers' guidelines.

Operator Requirements

A qualified operator for a fluoride removal water treatment plant requires thorough fluoride removal process training, preferably at an existing treatment plant. The operator must be able to service pumps, piping systems, instrumentation, and electrical accessories. The operator must be totally informed about the characteristics of sulfuric acid in all concentrations and sodium hydroxide in all concentrations. Safety requirements as to clothing, equipment, and antidotes must be thoroughly understood and executed. The operator must be trained to run routine water analyses including at least two methods for determining fluoride levels. He needs simple mathematics for record keeping during a treatment run and for operation cost accounting. Above all, the operator must be dependable and conscientious.

Cost of Operation

The cost of operating an alumina fluoride removal system including chemicals, electricity, bed replacement, replacement parts, and labor, currently falls in the range of 2-5¢/kL (8-20¢/1000 gal) of treated water. Individual plant operating costs vary as functions of raw water fluoride level, plant capacity, treated water consumption, electric utili-

ty rate, labor costs, delivered chemical costs, and so forth. The low operating costs at the three operational plants discussed in this article are shown in Table 3. The 1977-78 materials and construction costs for the plant at Gila Bend were less than $200 000. The plant was designed for 2.8×10^3 m³/day (0.75-mgd) average production with peak capacity of 4.8×10^3 m³/day (1.3 mgd).

Conclusion

Low operating costs for removing fluoride from potable water can be achieved with an activated alumina system. Reliability of plant equipment, materials, and operational costs have been documented through nine years of commercial field experience. Installation and operating costs are compatible with limited public budgets and funding programs. All materials and equipment are available, and there is existing technology to assist in designing a plant to meet fluoride MCLs.

EXPERTISE AND ENGINEERING

Unquestionably, the world expert on flouride removal is:

RUBEL AND HAGER, INC.
4400 East Broadway
Tuscon, AZ 85711
(602) 327-6616
Frederick Rubel, Jr., P.E.

His excellent design manual "Removal of Fluoride from Drinking Water Supplies by Activated Alumina," EPA Report No. EPA-600/2-84-134 of August, 1984, is available from:

NATIONAL TECHNICAL INFORMATION SERVICE
Springfield, Virginia, U.S.A.

ROOIBERG MINERALS DEVELOPMENT CO. LTD.

In 1984, two water defluoridation plants, each of 518 m^3/d, were installed to treat minewater containing 6-10 mg/l F as described in Appendix I.

In this case, the original testwork was carried out by the National Institute for Water Research. Final design and construction was by:

PRENTEC (PTY) LTD.
Post Office Box 1433
Edenvale 1610

609-5216
John A. Buchanan

Capital investment for the two plants including the reticulation system was R0.75 million. Operating costs are estimated at U.S. \$0.20/m^3 U.S. \$0.76/1000 U.S. gallons which is relatively high even taking into account that these are smaller plants with higher relative overhead, and the cost includes engineering and taxes.

In this case, the regeneration wastewater is used to pump tailings to the tailings dams.

INTRODUCTION

Iron occurs in solution as ferrous and/or ferric ions depending on pH and dissolved oxygen concentration. At neutral pH and in the presence of oxygen, soluble ferrous iron (Fe^{2+}) is rapidly oxidized to ferric iron (Fe^{3+}) which readily hydrolyzes to form the insoluble precipitate ferric hydroxide $Fe(OH)_3$.

Below pH 6, the rate of ferrous iron oxidation to ferric is extremely slow. Therefore, acid and/or anaerobic conditions are necessary for iron to exist in solution.

In addition, at pH values above 12, ferric hydroxide will redissolve due to the formation of the $[Fe(OH)_4]^-$ complex anion. Also, even in acidic, anaerobic conditions, if a source of sulfide ions is present, iron will be removed from solution as FeS or Fe_2S_3. Ferric and ferrous ions are also solubilized in the presence of cyanide due to the formation of ferri- and ferrocyanide complexes. Such complexes present considerable difficulties for both iron and cyanide removal. Since the sulfide precipitates are more stable than the cyanide complexes, however, addition of sulfide to polish solutions may offer one possible way to remove iron and to render any cyanide ions amenable to oxidation if necessary.

Ferrous ions and ferrous hydroxide are greenish in color. Ferric ions in solution are yellow, but when ferric hydroxide precipitates, the precipitate is red-brown and gelatinous. Acid mine drainage in contact with air turns red brown in color because of the suspension of colloidal ferric hydroxide particles.

Acid mine drainage, which includes water draining or pumped from both underground and open pit mines, seepage and runoff from mine wasterock, tailings ponds, and surface runoff from any area affected by mining (e.g., concentrate stockpile areas, mine-mill-smelter yards, roadbeds, and rail beds constructed with wasterock, etc.), usually contains iron often with minor amounts of other metals, e.g., Cu, Zn, Ni, and Mn.

Iron in acid mine drainage often helps in the removal of other metals because it acts as excellent co-precipitant. However, ferric hydroxide is a gelatinous, difficult to settle precipitate usually with a very low terminal solids density which requires large lagoons for disposal unless special measures are adopted.

OCCURRENCE OF IRON

Surprisingly, iron contamination of water occurs prolifically around mines other than iron mines. Acid mine drainage is one of the most formidable challenges facing the mining industry. It affects base metal mines, especially massive sulfide deposits, uranium mines particularly of the Elliot Lake and Witwatersrand type, gold and silver mines associated with sulfides and, of course, the enormous coal mining industry. It is the ubiquitous occurrence of iron sulfide minerals, e.g., pyrite, pyrrhotite, and marcasite, that generates acid mine drainage on oxidation.

Acid mine drainage inhibition and treatment has been discussed in separate chapters, and most of that discussion would be applicable to this discussion on iron removal.

Iron sulfide minerals may comprise only 1-3% of a mine tailing, or they may be as much as 95% of a tailing material. Both generate acid mine drainage.

In waters of low dissolved oxygen, iron may be reduced to the ferrous form, and some iron may be in solution as the ion. Ferrous iron may be released from lake sediments if the water above the sediments becomes totally anaerobic; the release of iron is the result of a shift in the redox potential below a critical level at the sediment surface according to ONTARIO MOE (1974).

ENVIRONMENTAL IMPACT OF IRON

Iron is an essential mineral constituent for just about all life forms.

In the public water supply, soluble iron at levels in excess of 0.3 mg/l Fe can cause staining of tile surfaces.

Excessive levels of iron in drinking water (around 0.5 ppm and more) start to impart a flavor to water, and 1.0 mg/l Fe is cause for rejection as drinking water.

Iron in receiving waters (lakes and streams) interferes with aquatic biota. It is the fouling properties of iron hydroxide that apparently does more damage than soluble iron in water. There are several types of impact:

1. impairment of fish larvae respiration.
2. Impairment of gill action through fouling.
3. Impairment of streambed habitats by formation of ferricrete.
4. Fouling of streambed plants and algae.

It is concluded that iron released into the aquatic environment will almost always be precipitated. Fine flocs formed at low iron concentrations may sometimes do more damage than large flocs formed at higher iron concentrations.

The criteria for total iron levels in freshwater at which the environment is protected is 300 ug/l total iron in Canada, and 1,000 ug/l total iron in the U.S.A. U.S. EPA (1972), CANADA (1979).

In the marine environment, a criteria level of 300 ug/l has been set by U.S. EPA (1972). ONTARIO MOE (1979) provides a lengthy discussion on the effects of iron on several aquatic algae and organisms which was found to be highly variable. Below 300 ug/l Fe, it was concluded, all aquatic species would be protected since below this level iron flocs would be unlikely to form.

Another environmental effect of iron in solution is the pH reduction that occurs during the hydrolysis of ferrous to ferric iron.

REGULATORY LIMITS FOR IRON

In reviewing the permits for discharge of effluents encountered during the course of this investigation, it was found that iron is not very often included. The only cases found which limit iron levels in their discharge are as follows:

	Iron Total Limit (mg/l)
Mount Emmons, Colorado NPDES	1.0
NORANDA Grey Eagle Zero Discharge Except Excess Water Can Be "Irrigated" After Treatment	0.20
Climax Molybdenum, Climax, Colorado	0.60
Typical Arizona Copper Concentration	
25-Hour Max.	1.00
30-Day Ave., Max.	0.50
Public Water Supply, U.S. EPA (1976)	0.30
Public Water Supply, Canada (1979)	0.05
South African Drinking Water SABS (1971)	
Recommended Maximum	0.10
Rejection Limit	1.00

TREATMENT FOR IRON

The most usual treatment process for iron is oxidation to ferric and precipitation of ferric hydroxide near pH 7 where the solubility of iron is at a minimum. Often, when other metal ion contaminants must be removed as well, a somewhat higher pH is employed.

Fe (ug/L) IRON

Summary of North American Water Quality Criteria for Iron

Compiled by NORANDA

FIGURE 14.—Fields of stability for solid and dissolved forms of iron as function of Eh and pH at 25°C and 1 atmosphere of pressure. Activity of sulfur species 96 mg/l as SO_4^{-2}, carbon dioxide species 1,000 mg/l as HCO_3^-, and dissolved iron 0.0056 mg/l.

At pH 7.0-7.5 and above, conversion of ferrous to ferric iron occurs very rapidly as described in the section on acid mine drainage treatment. Spontaneous formation of ferric hydroxide then results in iron removal by precipitation.

JOBIN and SHOSH (1972) found that the rate of ferrous oxidation is dependent on pH, buffer intensity in bicarbonate systems, and upon the concentration of organic matter. Organic compounds containing hydroxyl and carboxyl functional groups seem to greatly reduce oxidation rates and can result in high soluble iron levels if the organic substances do not readily break down.

If iron is present in acid waters as the ferric ion, simply neutralizing the acid will precipitate the iron.

In some cases where there is a significant quantity of dissolved CO_2 in the water, this will be present as bicarbonate HCO_3^- in the acidic water. The bicarbonate/carbonate system buffers the water and consumes more lime than would otherwise be required to increase the pH over 7. By vigorous aeration of the water to remove CO_2 from solution, it is possible to reduce the amount of lime needed to modify the pH and precipitate iron. This process is applied at BETHLEHEM STEEL CORP.'s Panther Valley Division anthracite coal mine water treatment plant.

Iron removal from municipal water supplies has been practiced for many years. Iron levels in ground water supplies are characteristically 1-10 mg/l as ferrous iron. Ground waters are typically anoxic and weakly acid, usually high in CO_2. Aeration to remove CO_2 (and consequently increase pH) and to oxidize ferrous to ferric comprises the standard municipal water treatment. Lime is frequently employed for additional pH adjustment. The following table summarizes the treatment performance for some municipal iron treatment plants as reported by PATTERSON (1975).

SUMMARY OF MUNICIPAL PLANT PERFORMANCE FOR IRON

Process	Iron Concentration mg/l		
	Influent	Effluent	Reference
1. Chlorination, Alum-Lime-Sodium Silicate Precipitation and Sand Filtration	1.5	0.05	HANEY (1964)
2. Aeration, Lime, Sand Filtration	2.4	0.0	HANEY (1964)
3. Aeration, Sand Filtration	2.5	0.13	GARDNER and STIKA (1964)
4. Aeration, Coke Bed Filtration, Sedimentation, Sand Filtration	5.7	0.13	McCRACKEN (1961)
5. Lime, Aeration, Diatomite Filtration	10	1.10	KOLLIN (1962)

In the treatment of acid mine drainage, it is usually necessary to neutralize relatively high concentrations of acid and to precipitate considerably higher concentrations of iron;

this consumes much more lime and generates much larger volumes of precipitate sludges which must be disposed of.

TREATMENT OF IRON IN ACID MINE DRAINAGE

Treatment Chemical	pH	Initial Iron (mg/l)	Effluent Iron (mg/l)	Reference
Limestone Slurry		145	5	PATTERSON (1975)
Lime		157	1.6	PATTERSON (1975)
Soda Ash		126	2.3	PATTERSON (1975)

During the course of this investigation, the following iron removal results were idendified:

Operation	Reagent	Treatment pH	Iron in Influent (mg/l)	Iron in Effluent (mg/l)	Plant Capacity
AMAX, Mount Emmons	Lime, F_L, F	10.6	27-800	0.05-0.30	11,000 m^3/d
Brunswick Mining	Lime, D	9.03	951	2.35	
ERPM - Rand Mines	HDS	7.3	650	Nil	50,000 m^3/d
ERPM - Rand Mines	R.O. Pilot	4.5	6.0	0.06	5 m^3/d
Falconbridge, Onaping	Limestone, D	7.0	2-4	0.04-0.60	-
Gilman, Colorado	Lime, D	9.60	50-180	0.10-1.20	500-700 m^3/d
INCO, Copper Cliff	Lime, S	10.0	13.4	0.35	272,000 m^3/d
JABILUKA Uranium	Lime, S	8.0	2,000	1.0	-
Noranda, Waite-Amulet	Lime, HDS	9.80	254	1.40*	4300 m^3/d
Ontario Cu, Pb, Zn Mill G	Lime, HDS	8.9	676	0.77	4300 m^3/d
Ontario Cu, Pb, Zn Mill M	Lime, S	10.2	4.70	0.48	4000 m^3/d

* Drops to 0.30 mg Fe/l in polishing pond decant.

LIME: Lime Neutralization
FL: Precipitate Flotation
F: Multi-Media Filtration
D: Decantation

HDS: High Density Sludge Process
S: Settle in Thickener-Clarifer
R.O.: Reverse Osmosis

TREATMENT COSTS

Operation	Plant Size	Cost/m³	Capital
INCO Copper Cliff	272,000 m³/d	US $0.06/m³	C $4.1 Million (1975)
Eastern Canada Mine #6	2,900 m³/d	US $0.60/m³	
Falconbridge, Sudbury	16,000 m³/d	US $0.01/m³ (1979)	C $257,000 (1978)
R. Osmosis	Conceptual	US $0.50/m³	

DISCUSSION

1. The HDS process described in Appendix I in trip reports for:

   RAND MINES, ERPM
   KROMDRAAI COAL MINE
   NORANDA, GECO
   NORANDA, WAITE-AMULET

   The HDS process offers a significant advantage in the treatment of acid mine drainage containing high levels of iron in that a dense, stable sludge can be produced which is compact and safe to dispose of and non-amphoteric.

2. In the section on acid mine drainage, HDS application at several additional operations is discussed in which sludges with up to 50% solids are generated.

3. BETHLEHEM INTERNATIONAL ENGINEERING CORP., Bethlehem, Pennsylvania, has shown that HDS sludge from acid mine drainage yields a stable waste material when mixed with a pozzolan that is suitable for landfill disposal.

4. The Wannamaker Continuous Concentrator has been demonstrated for acid mine drainage treatment from the Argo tunnel. This is a form of cross-flow micro-filtration technology using sludge recycle which also achieves a relatively low iron value in the treated effluent and a precipitate with a higher percent of solids.

5. The USBM at Pittsburgh has shown the effect of a natural bog in raising the pH of acid mine drainage and precipitating iron as ferric hydroxide.

6. BARRET, HAENTJENS AND CO. of Hazelton, Pennsylvania, has developed a new jet pump which effectively flash-precipitates iron from acid mine drainage at a lower pH. This device is described in the section on AMD treatment.

7. Although various processes will be needed to polish effluents from mining and milling operations, the magnitude of the acid mine drainage problem is so great that attention will have to focus on prevention of the problem rather than treatment technology.

8. It was pointed out above that neutralization of acid mine drainage to a pH in excess of 7.0 at which ferrous ions oxidize rapidly to ferric ions can be quite expensive. An interesting innovation in this respect was proposed and described by MIHOK (1969) who found in laboratory batch flow tests conducted with high iron acid mine drainage treated with activated carbon that the iron was rapidly catalytically oxidized by the activated carbon. The ferrous iron content of an acid mine water flowing through an aspirated activated carbon column was reduced from around 700 to 10 ppm in less than one minute at pH around 2.5.

   The activated carbon was used repeatedly with little loss in efficiency and no discoloration or solids deposition. In the batch tests, about one-third of the iron was adsorbed by the carbon, but with continuous flow, little iron adsorption is expected. (No reasons were given.)

   It was proposed that a catalytic oxidation step in the treatment of acid mine waters containing ferrous iron would facilitate neutralization providing precise control of pH, lower reagent costs, and elimination of aeration equipment. Also, limestone might possibly then be suitable for acid mine drainage neutralization which would result in further cost savings compared with lime, provided ferruginous coatings that passify limestone can ve avoided.

   Although this revelation was made in 1969, no commercial application has been identified. No reasons for this were identified. In the original tests, a commercial type coal-base activated carbon 12 x 40 mesh was used.

9. At Jabiluka Uranium, LEVINS (1979) reported levels of 2,000-5,000 mg/l Fe in acidic uranium ore leach tailings/raffinate waste at the Alligator Rivers region of Northern Territory, Australia. After adjustment to pH 8, the iron level dropped to 1 ppm. Several other contaminants are precipitated when lime is added to pH 8, including Al, Ba, Cr, Cu, Mg, Mn, Pb, U, V, Zn, P, Si, and SO_4, which all would accumulate in the precipitate sludge.

10. <u>Biological Oxidation of Ferrous Iron Aids Precipitation</u>: WICHLACZ (1985) described the kinetics of ferrous iron Fe(II) oxidation by attached bacteria in bench-scale

rotating biological contactors (RBC). Oxidation efficiencies of better than 80% were obtained over the range of Fe(II) mass loadings tested (0.14-2.34 mg Fe(II)/ cm^2/hr.). The amount of oxidation and the rate depended on a combination of influent and bulk fluid Fe(II) concentration as well as flow rate. A model describing attached bacterial growth and oxidation rate as a saturation function of substrate utilization was developed and tested. The maximum oxidation rate constant was proportional to flow rate, and the substrate concentration in the reactor varied with influent substrate concentration. The model allowed prediction of metabolic constants and included terms for both constant and growth rate dependent maintenance energies.

Toward the end of Chapter 25 on "Removal of Contaminants," reference is made to additional testwork in which rotating biological contactors have been used to oxidize ferrous to ferric.

11. Dissolved Air Flotation: An expensive aspect of neutralization and precipitation plants is the removal of the iron hydroxide precipitate. Clarification plants are sized for the hydraulic flow rate pretty much regardless of the precipitate loading being removed from suspension. BOSMAN (1983) of the ANGLO AMERICAN RESEARCH LABORATORIES pointed out that for low precipitate loadings, dissolved air flotation can offer a much more compact clarification step. Since the volume of precipitate in such cases is small in any case, solids density of the floated concentrate is pretty much irrelevent.

    This aspect is also discussed in chapters 12 and 24 on removal of suspended solids and acid mine drainage treatment.

12. Reverse osmosis using the seeded slurry innovation has been successfully demonstrated at RAND MINES LTD. ERPM mine as described in the Appendix I trip report. At pH 4.5, a 95% plus water recovery was achieved, and the iron content was reduced from 6.0 ppm to 0.06 ppm. WILMOTH and SCOTT (1976) found that Fe^{2+} ions could be removed from 64 ppm to 0.5 ppm in their tests of R.O., also yielding a product water at pH 4.5.

    A summary of the results achieved by WILMOTH and SCOTT (1976) is provided in the following table:

Chemistry Analyses Illustrating Effluents from Various Processes to Treat AMD

Sample	*Cond*	*Acid*	*pH*	*Ca*	*Mg*	*Total iron*	*Fe^{2+}*	*Na*	*Al*	*Mn*	*SO_4*	*Alk*	*TDS*
Example One - Limestone Neutralization: Ferrous(A) versus Ferric(B) Using No Coagulants													
Raw feed A	4,000	610	5.2	360.	110.	270.	260.	480.	5.4	5.9	3,000	12.	4,200
Feed B (H_2O_2)	4,000	590	3.1	340.	95.	270.	0.	440.	8.2	5.9	2,500	0.	3,500
Effluent A	4,000	230	6.5	420.	90.	150.	150.	380.	1.0	5.8	2,400	88.	3,500
Effluent B	4,000	13	6.5	380.	70.	6.2	0.	370.	1.2	5.0	2,000	50.	2,900
Example Two - Limestone Neutralization with Extended Aeration, Sludge Recycle, and Coagulant Addition													
Raw feed	3,650	460	5.5	370.	110.	230.	220.	470.	12.	5.4	2,800	8.	4,000
Effluent	3,650	0	7.4	520.	110.	0.9	0.	440.	0.4	3.9	2,700	47.	3,700
Example Three - Lime Neutralization Comparing *p*H 8(A) versus *p*H 7(B) Using Coagulant Addition													
Raw feed	4,000	520	5.7	400.	130.	280.	260.	510.	9.8	6.4	3,200	23.	4,500
Effluent A	4,100	0	7.9	600.	120.	2.1	0.	500.	0.4	1.6	3,300	88.	4,700
Effluent B	4,100	0	7.0	620.	120.	10.	0.7	490.	0.6	4.9	3,300	50.	4,400
Example Four - Combination Limestone-Lime Treatment(A) versus Lime Treatment(B) Using Coagulants													
Raw feed	3,600	630	5.2	340.	100.	290.	270.	380.	15.	3.4	2,700	4.4	3,800
Effluent A	3,500	0	8.0	560.	83.	2.3	0.	370.	0.5	2.2	2,500	100.	3,500
Effluent B	3,500	0	8.0	560.	95.	1.4	0.	360.	0.2	1.2	2,500	110.	3,500
Example Five - Lime-Soda Treatment Where Effluent Hardness Is Less Than 100 mg/liter													
Raw feed	820	170	3.0	28.	18.	17.	—	1.8	13.	4.5	270	0.	350
Sed. eff.	930	0	11.	140.	1.1	0.8	—	1.8	2.7	0.2	240	100.	500
Softener eff.	1,000	0	10.8	41.	0.4	0.3	—	140.	2.5	0.05	220	110.	510
Recarb. eff.	790	0	9.2	33.	0.4	0.3		140.	2.4	0.06	220	74.	470
Example Six - Alumina-Lime-Soda Treatment													
Raw feed		700	2.8	8.	25.	100.	—	2.	40.	4.0	750	0.	950
Effluent		0	7.5	20.	10.	0.3	—	150.	0.2	0.04	250	—	450
Example Seven—Reverse Osmosis Treatment													
Raw feed	1,000	240	3.4	130.	90.	77.	64.	—	12.	12.	750.	0.	1,300
Waste brine	3,600	810	2.9	490.	310.	330.	250.	—	44.	24.	2,800.	0.	4,500
Effluent	17	32	4.5	0.5	0.6	0.5	0.5	—	0.2	0.08	2.2	0.	5
Example Eight - Ion Exchange Treatment (Design Values)													
Raw feed	—	240	3.4	130.	90.	77.	64.	1.0	12.	12.	750	0.	1,300
Cation eff.	—	800	1.9	13.	5.	6.	5.	3.	0.2	0.6	750	0.	800
Anion eff.		0	8.0	13.	1.5	1.2	1.0	20.	0.2	0.3	40	20.	110
Neu. eff.	—	0	7.5	20.	1.5	0.1	0.1	20.	0.2	0.04	50	30.	120

Note: All units are mg/liter except for conductivity (micromhos/cm) and *p*H. Alkalinity and acidity are expressed as $CaCO_3$.

It is noted in the above table that ferrous iron could be reduced using H_2O_2 as an oxidant and limestone from 270 mg/l to 6.2 mg/l, although the same solution with limestone addition and extended aeration reached pH 7.4 and iron was reduced to 0.9 mg/l.

CATALYTIC OXIDATION OF IRON

In Chapter 39 where removal of copper is discussed, a paper by FAULKNER (undated) describes how iron can be catalytically oxidized from ferrous to ferric with the use of SO_2 and activated carbon, even at an acid pH.

William D. Faulkner

KAIDA, et al. (1978) described a bench scale treatment of mine effluent containing iron, copper, Cd, and zinc. The process employs catalytic air oxidation of ferrous to ferric ions using $NaNO_2$, allowing fractional precipitation of ferric hydroxide prior to removal of other metals.

Both of these processes are petentially useful.

OCCURRENCE OF MANGANESE IN THE MINE-MILL ENVIRONMENT

Manganese, although not nearly as abundant as iron in rocks and soils, is nonetheless very abundant. Manganese frequently occurs in mine drainage and is often associated with zinc, copper, and silver ores. In South Africa, MnO_2 is used as an oxidant in uranium leaching with the consequence that Mn^{2+} can occur at high levels in uranium plant tailings and raffinates.

The PEDCO (1983) report which lists the findings of analyses of thousands of mine waste, mill tailings, and mine water samples from mines in the U.S.A., leads to the conclusion that manganese is relatively susceptible to the acetic acid leach tests from mined materials used in the EPA's EP leach test criterion for "hazardous waste."

MAREE and DEWET (1980) showed how manganese in the Vaal River suddenly increased in acidified river water from 140 mg/l to 4400 mg/l at Orkney, Transvaal, where it caused a problem in treatment for use as municipal service water. It was suspected at the time that seepage of gold-uranium mill effluents and runoff from manganiferous soils could have been responsible. Since then, manganese levels have dropped to much less than 1 mg/l as a result of advanced, yet simple, water management and practices by mines from which effluents drain into the Vaal River in that area. (Drainage from several mining companies enters the Vaal River upstream of Orkney.)

HILL (1972) reported manganese in mine waters at 1.2-8.0 mg/l, and KUNIN and DOWNING (1971) reported one acid mine drainage flow with 50 mg/l Mn.

At ENOXY COAL, INC., Buckhannon, West Virginia, coal waste is mixed with a carbonate rock to avoid the generation of acid mine drainage. Although the carbonate rock does inhibit the generation of acid, manganese in the carbonate waste rock goes into solution and reaches 30-150 ppm. This manganese is difficult to remove. To precipitate manganese, at a pH of over ten is needed; then the treated water must be pH adjusted to meet effluent pH limits, all of which require expensive reagents according to:

ENVIRONMENTAL SENSITIVITY OF MANGANESE

Manganese is undesirable in the public water supply. Even very low levels, manganese causes staining of plumbing fixtures and ceramic tilework.

The U.S. EPA (1972, 1976) shows a public water limit for manganese of 0.05 mg/l manganese. CANADA (1979a, b) has set a limit for manganese in the public water supply of 0.01 mg/l.

At 1.0 ppm Mn and more, the hatchability of trout eggs has been found to be affected.

The ONTARIO MOE (1979) discussion of the rationale for establishment of Ontario's Provincial Water Quality Objectives does not review manganese. The U.S. EPA and Canada do not define criteria for manganese at which the environment is considered protected. In U.S. EPA (1976), an objective of 100 ug/l Mn is established for marine water. The U.S. EPA does not state whether this is total manganese or soluble Mn.

Information on the toxicity of manganese to aquatic life (both freshwater and marine) is very limited. DAVIES (1981) found that the LC_{50} of manganese for trout in soft water ranged between 14.5 and 30.0 ug/l. The hardwater LC_{50} for 20 cm fish was 116 ug/l.

REGULATORY LIMITS FOR MANGANESE

Quebec has set a maximum limit of 0.05 mg/l for manganese in receiving waters. There does not seem to be any factual substantiation for this limit other than the fact that this limit is the same as for drinking water.

The U.S. EPA maximum permissible limit in marine waters is 0.10 mg/l Mn.

The U.S. EPA (1972, 1976) limit for the public water supply is 50 ug/l.

The South African Bureau of Standards (1971) standard for manganese in drinking water is 0.1 mg/l recommended and 0.4 mg/l maximum allowable.

The SOUTH AFRICAN GOVERNMENT GAZETTE (1962) does not list a limit for manganese in the General Limit for Effluents. However, in the SPECIAL LIMIT which was designed for effluents discharging into a list of specific creeks and rivers (supposedly those that are capable of supporting trout), a limit of 0.01 mg/l Mn was imposed.

During the course of this investigation, the only examples of Mn limits in effluents found were as follows:

MANGANESE-SOLUBILITY CONTROLS

The solubility of manganese in natural water and the predominant dissolved forms to be expected can be effectively summarized by means of Eh-pH diagrams.

FIGURE 18.—Fields of stability of solids and solubility of manganese as a function of Eh and pH at 25°C and 1 atmosphere of pressure. Activity of dissolved carbon dioxide species 100 mg/l as HCO_3^-. Sulfur species absent.

TREATMENT FOR MANGANESE

The solubility diagram for manganese in water inserted above was provided by HEM (1970) and indicates that to precipitate Mn^{+2} as a hydroxide, a pH of close to 12 is needed.

Of the various oxidation states of manganese, only the strongly oxidizing form permanganate and the divalent manganese in manganous ions are soluble in water.

Removal of soluble manganese has been practiced for many years in the treatment of municipal water supplies and industrial process waters.

Treatment technology basically involves the conversion of the soluble manganous ion to an insoluble precipitate. In water treatment, this generally means simultaneous removal of iron since conditions under which high iron levels occur in water supplies are essentially the same as for soluble manganese. Removal of manganese is achieved by oxidation of the manganous ion and by separation of the resulting insoluble oxides and hydroxides of manganese.

Because of the low reactivity of manganous ions with oxygen, simple aeration is not an effective oxidation technique below pH 9, and even above pH 9, the air oxidation reaction is slow according to WELCH (1963).

BORGREN (1962) found that organic matter in solution can combine with manganese and prevent its oxidation by simple aeration, even at a high pH.

OWENS (1963) showed the effect of pH on manganese removal by lime. A reaction above pH 9.4 is required to achieve significant manganese reduction.

Effect of pH on efficiency of manganese removal using lime.
[From Owens (7), courtesy of *Water and Sewage Works.*]

HILL (1972) reported that manganese can be reduced to less than 0.5 mg/l by simple neutralization and precipitation, but no pH values were mentioned. The use of calcium carbonate plus lime for iron and manganese removal from Japanese acid mine waters had proven successful.

The use of chemical oxidants to convey manganous ions to insoluble manganese dioxide in conjunction with coagulation and filtration has been recommended, although BORGREN (1962) reported that this may cause filtration problems. Apparently, the type of manganese flocs produced when strong oxidants are used tends to clog sand filters.

WELCH (1963) reported that manganese oxidation by chlorination may not be effective. OWENS (1963), on the other hand, reported removal of manganese at concentrations as high as 5.7 mg/l with chlorination followed by lime coagulation and rapid sand filtration. Sodium silicate was used as a coagulant aid. This is similar to the process currently in use by the Rand Water Board at their regional water supply treatment plant at Vereeniging, South Africa, which treats Vaal Dam water.

According to HARRIS (1962), effective manganese oxidation by chlorination requires a free chlorine residual of 0.5 mg/l and a dosage of 1.29 mg chlorine per mg manganese oxidized.

The successful use of potassium permanganate as a chemical oxidant has been reported. Addition of 1.5-2.0 mg/l of potassium permanganate reduced 1.0 mg/l of manganese to less than 0.05 mg/l according to HANEY (1964).

Permanganate requirement for oxidation of ferrous iron. [From Willey and Jennings (10), courtesy of American Water Works Association.]

Permanganate requirement for oxidation of manganous manganese. [From Willey and Jennings (10), courtesy of American Water Works Association.]

$KMnO_4$ was added 30 minutes upstream from the prechlorination point which was followed by lime-alum-sodium silicate coagulation (4-10 hours retention) and rapid sand filtration.

Since iron is generally present, the quantity of permanganate used must include that needed for oxidation of the iron content. The stoichiometric relationship between permanganate required and the quantity of iron and manganese present is shown in diagrams reproduced from PATTERSON (1975) above.

HOLLAND (1964) demonstrated the ability to remove manganese at lower pH with simultaneous removal of iron by permanganate oxidation. The addition of 0.04 mg/l sodium alginate reduced 0.35 mg/l manganese to less than 0.02 mg/l in the filtered supernatant. BORGREN (1962) further pointed out an additional advantage of permanganate over chlorination as the absence of residual taste or odor.

CONSTABILE and PERRON (1971) described the use of a vacuum diatomite filter in conjunction with permanganate oxidation for manganese removal from a municipal water supply. Manganese was reduced from 1.23 mg/l to 0.05 mg/l or less. The unit required 250 lbs. diatomite per million gallons filtered (30g diatomite/m^3).

Permanganate may be used indirectly for manganese removal in the manganese greensand filter method. The filter is a combination of New Jersey glauconite (greensand), manganese sulfate, and potassium sulfate which results in a filter bed of sand grains containing high oxides of manganese as described by WILLEY and JENNINGS (1963). Upon contact with manganous ions, an oxidation-reduction reaction occurs resulting in the formation of insoluble manganese dioxide which remains in the filter bed. The bed is periodically reoxidized with permanganate, and solids are backwashed from the bed. With this system, manganese was reduced from 1.7 mg/l to zero at pH 7.2 using a pressure greensand system (ALLING, 1963). This plant, with 500-700 gpm (2,700-3,800 m^3/d), cost only a third in capital compared with a conventional aeration, lime coagulation-clarifer-filter-recarbonation system. A permanganate dosage of 13 mg/l was used. The water had a manganese concentration of 13 mg/l manganese. Treatment costs in absolute terms are meaningless because it was so long ago, but these were comparable with lime costs for conventional treatment. This plant was continuously regenerated with periodic backwashing of the greensand filter. Generalized removal capacities for greensand filters are given as 0.09 pounds manganese per ft^3 of filter volume with regeneration requirements of 0.18 lb/ft^3 of $KMnO_4$.

Flow rates of 3 gpm/ft^2 are considered normal by ALZENTER (?).

NETZER, et al. (1975) investigated the use of ozone in conjunction with lime as a manganese removal technique in laboratory studies. The following results were reported by PATTERSON (1975) for solutions of manganous chloride initially containing 94 mg/l manganese:

[57] **ABSTRACT**

A process for removing manganese and chloride ions from an aqueous acidic sulphate solution containing zinc, manganese and chloride ions without removing a substantial amount of zinc ions from the solution includes adjusting the free acidity of the solution if necessary to at least about 0.1 molar. The solution is then treated with ozone to oxidize manganese ions to manganese dioxide, and the ozone treatment is continued after the manganese concentration has fallen to a low level to oxidize chloride ions to chlorine gas. The precipitated manganese dioxide is removed from the solution.

10.0	0.15	LT 0.1
11.0	LT 0.10	-

Ion exchange has been used for manganese removal, and many advantages are claimed by ALZENTER (?). PATTERSON (1975) pointed out one drawback of ion exchange as its non-selective removal of manganese with other ions. ALZENTER mentions performance of the IX plant over three years during which manganese in feedwater was routinely reduced from 1.7 ppm to 0.10 ppm Mn and less on a regular basis with iron removal from about 50 mg/l to 0.3 ppm Fe.

Brine was used for regeneration of the resin, and manganese remained in solution in the brine presenting a disposal problem. An anaerobic waste stream is necessary for the ion exchange system to avoid air oxidation of manganese in the feedwater with resultant precipitation and clogging of the ion exchange bed.

PATTERSON (1975) points out that the cost of the above processes for manganese removal from wastewaters may be increased by the presence of acids, other oxidizable metals, or organics in the waste stream. He points out that the unit operation costs for coagulation-sedimentation-filtration should be similar to those for iron removal systems. Additional costs are attributable for chlorine (or chlorine dioxide) and chlorination equipment plus lime needed to meet the higher pH.

During the course of this investigation, it was interesting that manganese was not monitored much of the time in effluents. In other cases, manganese removal required special conditions in water treatment.

MOUNT EMMONS, COLORADO

Manganese occurs in the old zinc mine water at 6.5-80 mg/l and in seepage from the stabilized tailings ponds at 400-500 mg/l. Through pH adjustment to pH 10.6, Lectroclear flotation of the precipitate, and multi-media filtration, Mn is reduced to 0.05 mg/l in the treated effluent.

Manganese removal requires a higher pH in the treatment plant than would otherwise have been needed.

Capital costs of this plant were $10 million, and operating costs for the 2000 U.S. gpm capacity plant run $700,000-1,000,000 per year operating at partial capacity.

An alternative means of removing precipitated metals that has been tested with promising results is dissolved air flotation.

GILMAN, COLORADO

Mine drainage from the underground zinc-silver mine located on the mountainside above the Eagle River runs 80-453 mg/l Mn. Originally, the ore was milled underground, and the tailings deposited to a tailings dam alongside the river in the valley below.

For years mine water has been segregated into a stream which requires treatment and one which does not. Treatment comprised raising the pH to 9.6 and settling in underground chambers to decant the water. However, during the 1970's, the Colorado Dept. of Health imposed an NPDES permit in which the maximum allowable manganese discharge is a level of 1 ppm.

The trip report in Appendix I includes reference to testwork by The New Jersey Zinc Company and the Colorado School of Mines Research Institute in which various oxidants were tested.

Although NaOCl was selected as the best oxidant from among $NaClO_3$, $K_2S_2O_8$, and H_2O_2, the amounts required were considered uneconomical in 1973. At that time, the addition of 1 lb. lime per 1,000 U.S. gallons of tailings effluent was deemed to be the best solution if operation of the mine seepage pumps were carefully synchronized with lime addition.

When 64 lbs. $Ca(OCl)_2$ equivalent were added per 1,000 U.S. gallons, manganese was dropped to 0.5 ppm Mn at pH 8.2. The addition of 22 lbs. of $Ca(COCl)_2$ equivalent and 23 mg lime per liter, reduced Mn to 0.9 ppm. Because $Ca(OCl)_2$ costs around $1.43/lb, it was concluded that this reagent would be uneconomical. Addition of 0.56 lbs. lime per 1,000 gal. resulted in a pH of 9.5 and reduced Mn to 1.1 ppm Mn, resulting in the conclusion that lime addition of 1.0-1.5 lbs. per 1,000 gal. would be the logical answer to reduce Mn to below 1.0 ppm Mn--cheap at 1.9 cents/lb lime at that time.

The Colorado School of Mines Research Institute showed that by passing the mine water through a column of crushed pyrolusite--which occurred in a vein in the mine--manganese levels could be dropped from 5 mg/l Mn to below 1.0 mg/l. The adsorption rate was shown to be a function of the manganese content of the feed solution and the retention time in the column. pH did not influence the adsorption rate in the range tested (pH 7.8-8.8). The pyrolusite adsorption of manganese II was found to be self-regerative to a degree. Mn II is adsorbed and in time oxidizes to $MnO_{1.3}$ and then to $MNO_{1.9}$ which is an adsorbent for incoming Mn II in solution. The granules in the column must be treated to restore permeability.

It was found that 1,000 gallons per minute of mine water containing 5 mg/l Mn II, a total of 5,407 m^2 of surface area would be required, or 32.8 tons of 1/2" x 1/4" pyrolusite. Assuming 120 lbs. per ft^3, this would require two 12 ft Ø tanks with 5' high beds of crushed pyrolusite.

It is believed that the pyrolusite adsorption tanks were never installed at the Gilman Mine. It is nonetheless of interest that the laboratory scale tests demonstrated the effectiveness of pyrolusite for Mn II removal from mine water at lower pH without the need for oxidation.

ENOXY COAL, INC.

At ENOXY COAL, INC., coal waste acid mine drainage is inhibited by adding a calcerous carbonate rock waste to the coal waste. This neutralizes any acid that is generated. However, although the AMD is neutralized and iron precipitated, manganese contained in the high $CaCO_3$ neutralizing waste goes into solution.

It was found that in solutions containing low levels of iron and up to 100-130 mg/l Mn II, it is very difficult and expensive to precipitate manganese. Randol International Ltd. recommended to ENOXY COAL that they test the HDS process.

THE HDS PROCESS

HERMAN (1984) of the BETHLEHEM STEEL CORP. showed at the Randol Workshop on Water Management that manganese can effectively be precipitated from acid mine drainage at a pH around 6.8 through the use of the high density sludge HDS process. In this process, lime is mixed with recycled sludge prior to being added to incoming acid mine drainage.

Manganese can be precipitated in this way even in the absence of iron.

A precipitate sludge is generated which lends itself to stabilization for landfill disposal by addition of a pozzolon. Apparently, if precipitated in the absence of iron, manganese redissolves readily unless stabilized in this manner.

More details on this process are available from:

BETHLEHEM INTERNATIONAL
ENGINEERING CORP.

Stewart T. Herman

RØSSING URANIUM LTD.

Manganese dioxide is used as an oxidant to dissolve uranium from RØSSING ore using a sulfuric acid leach at elevated temperature. Solution in the uranium tailings contains

2,000-2,500 mg Mn II/l at pH around 2. The tailings impoundment is porous, and seepage is collected by interceptor trenches. The natural rock and sediments contain carbonates which help to neutralize seepage solution. It is of interest that the seepage collected has pH 6.7, and the manganese level has dropped to 1100 ppm Mn.

In inspecting the trench faces, it is interesting to observe manganese oxide precipitating in the strata. Clearly, manganese oxides and hydroxides act as an excellent adsorbent for manganese from solution, even at relatively low pH.

Natural soils form good geochemical adsorbents for manganese: this property could undoubtably be exploited in special cases.

ORKNEY MUNICIPALITY, SOUTH AFRICA

River water from the Vaal River, when treated for use as municipal water by the municipal water treatment plant at Orkney (or Klerksdorp), Transvaal, was found in 1976 to be higher in manganese than the drinking water standard.

The National Institute for Water Research of the CSIR investigated various ways to remove manganese from this water. Their investigation concluded that:

1. The oxidation rate of Mn II is pH dependent.

2. The reaction Mn II and O_2 = MnO_2 is autocatalytic.

3. Measurable oxidation of Mn (II) by O_2 occurs only at pH in excess of 8.5.

4. Manganese is effectively removed from solution by adsorption on MnO_2. This adsorption is also pH dependent, requiring a pH of at least 7.7 to proceed at any pace.

5. Adsorbed metal ions on hydrated oxides are released when the pH is dropped.

6. The higher the amount of Cl_2 added, the faster the removal of manganese at around pH 7.

7. At 15 mg/l Cl_2 addition, the rate of Mn (II) removal is enhanced by increasing pH just one unit from 7 to 8.

8. Addition of 500 mg/l MnO_2 at pH 7.5 has a dramatic increase on removal of Mn (II) ions from solution.

9. In the presence of Cl_2, just 0.66 ppm $Mn^{+/}$ increases the rate of Mn II removal by 100%.

Eventually, it was found that allowing MnO_2 to coat filtersand in the filtration plant makes it possible to effectively precipitate manganese from the raw municipal water when it is filtered. The NIWR report with details has not been published. However, industry can approach the NIWR for help on manganese removal problems.

High manganese has been found in several other South African raw municipal water supplies.

VAAL REEFS EXPLORATION AND MINING CO. LTD., ORKNEY, TRANSVAAL

Manganese is used as an oxidant in acid uranium leaching on the Witwatersrand including Vaal Reefs. Typical uranium plant raffinates contain 1670 ppm Mn. Effluents from various Vaal Reefs plants are currently treated by mixing them with tailings pulps and adding lime to raise the pH to 9.5. A considerable amount of iron in the form of raffinate (730 ppm Fe^{2+}, 500 ppm Fe^{3+}) is added. This requires 10-12 Kg lime per ton which, at Vaal Reefs, costs R7.76 million/year in lime costs alone to yield a tailings dam decant solution with less than 1 ppm Mn.

Effluent neutralization in this way costs R0.80-R1.00 per ton ore treated which is a sizable percentage of total metallurgical costs, but allows zero discharge and recycle of all water that can be reclaimed.

Since the implementation of effluent neutralization at Vaal Reefs, the manganese level in the Vaal River water has been reduced to less than 1 ppm in the vicinity of the huge metallurgical complex.

RAND MINES LTD., ERPM SEEDED SLURRY R.O.

At the Hercules shaft of the ERPM Mine on the eastern Witwatersrand, a mine water was desalinated on a test basis in 1984 to demonstrate the seeded slurry reverse osmosis process.

Manganese levels were reduced from 8 mg/l in feedwater at pH 4.5 to 0.5 ppm Mn in the product water. This demonstrated a much higher tolerance to manganese than can normally be tolerated by membrane desalination processes, and a high water recovery in excess of 95%. More information on seeded slurry reverse osmosis is available from:

Fundamental to the success of seeded slurry reverse osmosis is the availability of a new cost effective tubular R.O. unit referred to in the chapter on reverse osmosis.

BUREAU OF MINES, PITTSBURGH, JET AERATOR

ACKMAN and KLEINMANN (1984) described a new in-line aeration and treatment system for acid mine drainage. The principle is to add NaOH solution via a nozzle to the acid mine drainage via a jet pump followed by a static mixer ahead of discharge to a settling pond.

Although NaOH is more expensive than lime, in this case the equipment simplicity would enable significant capital cost savings.

Manganese was dropped in demonstration runs by 50% from a level of around 70 mg/l. at pH 4-6, and almost quantitatively from the same solution at pH 7-9.

Commercial jet pumps for the purpose are now available as described in Chapter 24 on acid mine drainage treatment. More information is available from:

ARGO TUNNEL TEST, WANNAMAKER CONTINUOUS CONCENTRATOR

The Colorado Dept. of Natural Resources, Dept. of Mine Land Reclamation, demonstrated a device known as the Wannamaker Continuous Concentrator in 1981 to treat ARGO TUNNEL acid mine drainage containing 108 ppm Mn.

The precipitate was recirculated through the Wannamaker Continuous Concentrator as described by HOLM and SIMPSON (1981).

In this test, manganese was reduced to 0.65 ppm at pH 9.2 and to 0.005 ppm at pH 9.8. The proposed water standard was 1.1 ppm Mn.

J. David Holm

Randol International Ltd. believes that the effectiveness of manganese removal would be enhanced if the cross-flow filter were to be used in an HDS mode--ie., mixing the filtercake slurry with lime before it contacts the influent water to be treated.

DRY MGO PRECIPITATION OF METALS

SCHILLER and KHALAFALLA (1983) describe a patented process for removal of heavy metals and manganese from wastewater employing a substantial excess of essentially dry powdered reactive MgO as the precipitant. The resulting precipitant settles rapidly to a small volume of solids which is not readily redispersed or redissolved. A water product with low suspended solids can readily be recovered by decantation. More information can be requested from:

SULFIDE PRECIPITATION

LARSEN and ROSS (1976) showed the effect of addition of lime and then Na_2S to acid mine drainage containing various metals including manganese.

It is of interest that manganese is one of the last metals to be precipitated in this way, and, even after 700 ml solution containing 0.1M Na_2S was added to an AMD sample containing 126.3 mg Mn/l, all manganese had still not been precipitated.

Two-stage process chemically treats mine drainage to remove dissolved metals

H. Peter Larsen and Laurence W. Ross, University of Denver

Fig. 1—Field treatment system for mine drainage

TREATMENT OF MINE DRAINAGE WATERS has fast become a necessity for all mining operations, and regulations governing discharge into local waterways can be expected to become even more stringent. One aspect of mine water treatment—removal of dissolved metals—can be accomplished by a two-stage process developed at the Denver Research Institute (DRI). The first stage of the process treats the waters by lime neutralization to eliminate Fe and Al. A second stage then removes Cu, Zn, Mn, and heavy toxic metals (Hg, Cd, As) by adding sulphide to the waters.

The quantitative effect of both stages of treatment can be predicted by a mathematical description based on the equilibrium relations involved:

$$mM^{+d} + dD^{-m} \rightarrow M_mD_d \downarrow \qquad (1)$$

where M is the metallic cation of charge $(+d)$ and D is the anion of charge $(-m)$.

The removal of dissolved metals by neutralization (stage 1) is predicted quantitatively. Total sulphide addition to achieve removal of specific metals is predicted for stage 2.

Table 1 provides the set of numerical constants used to describe the system mathematically. These values were selected from the literature as yielding the best approximation to measured results. Butler[1] has pointed out that K_{sp} values are often so small that they are outside the realm of realistic measurement. Therefore, a set of values that gives consistent results is all that is needed.

DRI process successful in field studies

Field investigation for the DRI process included erection of a treatment pond beside Mineral Creek in the

Regulatory authorities in most industry centers are "paranoid" about mercury and not without some justification. Mercury poisoning has resulted in an extremely unpleasant and even fatal illness in some of the people who worked with mercury in the past and also to people who ingested mercury via the food chain. Memories of contaminated tuna and the tragic Minamata Bay accident in Japan which resulted from an industrial discharge of an effluent containing mercury are still fresh in our minds.

Mercury can be a problem in the workplace when allowed to build up in recirculating metallurgical process solutions; for example, in zero discharge gold and silver recovery operations. Restrictions on mercury in mine-mill effluents are very strict indeed to protect aquatic life.

Mercury occurrences in nature are common especially in and around mineralized zones, particularly of volcanic origin (epithermal), gold and silver deposits and base metal deposits. Mercury also occurs as a primary resource and is often enriched in soils around mineralized zones even where base metals may be only weakly enriched.

During the late 1960's and early 1970's, mercury was considered to be a likely pathfinder element in mineral exploration. Numerous techniques were developed to analyze mercury in soils and soil gas, but the ultimate result was that mercury anomalies occur so much more frequently than mineral deposits that this technique has not become widely applicable.

Mercury probably occurs more often than it has been recognized in the effluents of mine-mill complexes. There are reliable quantitative ways to monitor the air in the work environment, but the EPA limits for mercury in water are so low that they are well below the best analytical techniques.

OCCURRENCE OF MERCURY IN THE MINE-MILL ENVIRONMENT

Based on data contained in the PEDCO (1983) report to the EPA, mercury levels in mine and mill effluents and leachates seldom exceed one ppm and are usually in the ppb range or less. A summary of their data for mercury has included below.

Historically, mercury was extensively employed for amalgamation recovery of gold from both placer and lode deposits but its use has now been almost entirely replaced by other processing methods. Mercury poisoning was apparently not all that uncommon among workers who operated amalgamation plants or amalgam treatment facilities. Even in recent times, amalgamation was used at the DUVAL CORP.'s Battle Mountain operation and at HOMESTAKE's Lead operation. At Lead, amalgamation of slimes has been entirely replaced by cyanidation leaching and carbon in pulp. At Battle Mountain, amalgamation has been replaced by the installation of jigs ahead of cyanidation to catch coarse gold. There are

still numerous plants in South America and South Africa which employ amalgamation to treat gravity concentrates as do small placer operations in Alaska, although in South Africa the trend is increasingly toward intensive cyanidation and electrowinning.

Mercury dissolves in alkaline cyanide solution with the result that if solutions are to be recycled, mercury levels can build up despite the fact that it generally follows gold through zinc dust precipitation into the precipitate or also through carbon adsorption and electrowinning.

Mercury is consequently recovered as a minor by-product at several gold mining operations including the CARLIN GOLD MINING CO., Nevada; PUEBLO VIEJO, Dominican Republic; PINSON GOLD MINING CO., Winnemucca, Nevada; and at FREEPORT GOLD, Elko, Nevada, to name a few.

When mercury is present in a milled ore, it may build up in solution as process water is recycled. If zinc precipitation is used, then mercury must be retorted from the precipitate and recovered prior to smelting. If carbon adsorption processes (either carbon columns for solution or CIP for slurries) are to be used, then mercury can report in the plant around the carbon regeneration kiln, the electrowinning cells, and over the elution vessels, as well as around the steel wool cathode smelting operation. In metallurgical solutions, mercury levels are likely to increase until an equilibrium level is reached and maintained. Interestingly enough, it is not only epithermal deposits that contain mercury. The Witwatersrand fossilized placer deposits also contain low levels of mercury along with other metals, but studies by the Chamber of Mines of South Africa have concluded that these present no cause for alarm from a safety or environmental standpoint.

In California, where PLACER SERVICES, INC. employs a dredge to rework an old placer deposit by digging deeper, amalgamation is used for gold recovery. However, more mercury is recovered than lost in the process. In this case, previous operations left mercury in their tailings which is now being recovered in PLACER SERVICES' more efficient gravity process.

Based on the PEDCO (1983) report data, mercury in copper, lead, zinc and other operations is generally present at very low levels. This data is relatively "spotty," but it is the best currently available. In some gold cyanidation operatons, the mercury levels undoubtably reach levels in the tens and likely in the hundreds of ppm.

PEDCO (1983) DATA SUMMARY - MERCURY

URANIUM - NEW MEXICO

All minewater and both acetic acid and water leach of solids are reported as less than 0.0005 mg/l Hg.

URANIUM - WYOMING

Surface mine waste acid leachate reached a maximum of 0.046 mg/l and a minimum of less than 0.0001 mg/l Hg. Acid leaching of low grade ore containing 0.046 mg Hg/Kg ranged between a maximum of 0.014 mg/l and a minimum of 0.0001 mg/l. All other leachates ranged between 0.0008 mg/l and less than 0.0001 mg/l Hg.

URANIUM - OTHER

Mercury levels are somewhat higher in this district as illustrated by the following summary although still well below the criterion of 0.2 mg/l.

Levels of up to 0.027 mg/l Hg were encountered in the aqueous leachate from surface mine waste and 0.046 mg/l Hg in the acid leachate from underground mine waste, and minewater pond liquid and untreated mine water are shown at less than 0.0076 mg/l or 8 ppb Hg.

WESTERN LEAD/ZINC DISTRICT

The average mercury in underground mine waste is shown as 0.34 mg/Kg with less than 0.00005 mg/l Hg in the acid leachate and an average of less than 0.0051 mg/l in the aqueous leachate. The maximum level in mine backfilled tailings aqueous leachate was 0.048 mg/l.

EASTERN LEAD/ZINC DISTRICT

Tailings pond liquid varied from less than 0.0002 mg/l to 0.0018 mg/l Hg. Tailings pond settled solids ranged from 0.01 g/t Hg but maximum acid leachate and water leachate reached 0.032 and 0.102 mg/l respectively. Averages were 0.0077 mg/l and 0.0303 mg/l.

MISSOURI LEAD/ZINC

Only one leachate, the aqueous leachate from tailings pond settled solids, exceeded 1.0 ppb at 0.0011 mg/l Hg. All the rest were very low, in the range 0.0002-0.0008 mg/l.

MOLYBDENUM

Tailings pond liquid and untreated mine water are listed at less than 0.0076 mg/l Hg, but the report does not specify how low.

NEVADA GOLD/SILVER DISTRICT

Not surprisingly, mercury reaches somewhat higher levels in leachates from gold and silver milling operations, but considering the known association between mercury and gold-silver orebodies, it was surprising that the leachable levels were not even higher.

Aqueous leachate from surface mine waste ran 0.022 mg/l Hg. Tailings pond liquid interestingly enough varied between 0.358 and 0.526 mg Hg/l, probably reflecting mercury leached in the cyanidation process. Even tailings pond solids run between 0.0025 mg/l and 0.0415 mg/l Hg.

Even though the EP toxicity test criteria were not exceeded by the leach test, decanted tailings pond liquid exceeded the EP leach test criteria for mercury in some cases.

OTHER GOLD/SILVER DISTRICTS

In this area, leach test results for three samples yielded less than 0.0011 mg/l Hg, but tailings pond liquid ran 0.0423 mg/l, and the acid EP leach test with acid from settled solids in the tailings pond exceed 5.7 mg/l. It is clear that from one gold mining district to another, there are major changes in mercury levels and also in the amount of mercury that is acid and water soluble.

TACONITE DISTRICT

Even in the taconite district, mercury levels in ore are higher than one might expect at 0.0013 mg/l in acid leachate. Although not a high level in itself, the acid leachate exceeds 1 ppb.

In the course of this investigation, it was surprising how seldom mercury is monitored on a regular basis; it having been determined in the past (it is assumed) that mercury levels are of no consequence in the effluents. The only references to mercury monitoring in mine and mill effluents encountered are as follows:

	Effluent Hg (ppb)	Permitted Hg (ppb)
Kidd Creek Mines, Timmins		
- Underground Mine Drainage	LT 1	
- Treated Mine Drainage in Holding Pond	LT 1	
- Recycled Minewater	LT 1	
- Kidd Creek Water After Mixing with Treated Water	LT 1	
Mount Emmons Operation, Climax Molybdenum Division		
- Maximum Permissible Limit (Daily)	0.05	0.05
- Measured in Treated Water Discharge	LT 0.20*	

	MERCURY	
	Effluent Hg (ppb)	Permitted Hg (ppb)
Kidd Creek Concentrator, Timmins		
- Tailings Decant After Lime Treatment	LT 1.0 ppm	

* Detection Limit

Most gold and silver recovery operations located in the western U.S.A. are "zero discharge" operations and consequently, effluent limitations do not apply as there is no effluent. These operations would be expected to have somewhat higher mercury levels in their recycled process solutions.

BYCROFT, et al. (1982) reported on mercury contamination of the Lerderberg River, Victoria, Australia, from an abandoned gold field. This paper was not obtained but could be requested from the authors at Monash University, Clayton.

PATTERSON (1975) refers to observations that caustic soda manufactured by chloralkali processes that use mercury may contain "very high" levels of mercury. Literature references report mercury levels of 0.2-150 mg/l in caustic solutions. Caustic from Swedish chloralkali plants contained an average of 3.26 mg/l Hg. Considering the very low levels of mercury allowed in effluents, even the possibility of levels of this magnitude in caustic soda reagents must be taken into account where caustic soda is used for pH adjustment. The addition of 0.3 lb. caustic per ton of solution, for example (150g/t), would add 1 ppb Hg to the effluent which is of the order of the maximum level permitted in mill effluents.

It is possible, but not confirmed, that environmental concerns about mercury losses in chloralkali plants may well have resulted in steps to reduce levels in caustic soda product since PATTERSON (1975) reported the results.

REGULATORY LIMITS FOR MERCURY IN EFFLUENTS

Objectives and maximum permissible limits for mercury in receiving waters are listed below. It is interesting that the MINISTRY OF THE ENVIRONMENT OF ONTARIO (1979) has set two objectives. First is a concentration of 0.2 ug/l Hg of total mercury in filtered water and second, a maximum level of 0.5 ug/g Hg in whole fish (wet basis) for the protection of aquatic life and fish-consuming birds as well as the human consumer.

TABLE

MERCURY

The U.S. EPA criteria objective for mercury in receiving waters for the protection of the environment has been set by the U.S. EPA (1980) at 0.00057 ug/l with a maximum permissible concentration of 0.0017 ug/l.

Since the detection limit of most commonly used analytical measuring instruments is much higher than this, the U.S. freshwater criteria are considered unrealistic. The U.S. objective and maximum permissible concentration are also well below background levels in many streams and lakes. The most sensitive detection equipment in common use is the U.V. detection system employed in the flameless atomic absorption cold vapor technique. This method has an accepted detection limit of 0.01 ug/l as Hg. Although the detection limit can be decreased to 0.001 ug/l, accuracy at this level is poor, and at such extremely low levels, there is no way of knowing whether the mercury measured is in fact in the water or introduced from other sources, e.g., adsorption on the walls of the laboratory glassware. Possibly the objective is meant to be regarded as a target with no serious intention of ever meeting it; the basis for the U.S. mercury objective and maximum permissible concentration is not known.

WATER QUALITY CRITERIA FOR MERCURY

Freshwater	Hg (ppb)
U.S. EPA (1980) Max. 24-Hour Average Hg Objective	0.00057
U.S. EPA (1980) 24-Hour Mean Max. Permissible	0.0017

SOUTH AFRICA (1971) Drinking Water Max. Allowable	10

MERCURY LIMITS IN MINE-MILL OPERATING PERMITS

Most of the operations visited did not have a stipulated mercury limit in their effluents because, in most cases, mercury was not deemed to be a problem. The few cases where mercury limits were included in the permit are as follows:

	Hg (ppb)
HOMESTAKE MINING COMPANY, Lead	
- Final Effluent (NPDES)	1.0
HOMESTAKE - McLaughlin Project	
- Treated Runoff Water, 30-Day Ave.	1.0
- Treated Runoff Water, Daily Max.	2.0
AMAX, INC., Mount Emmons	
- Final Effluent After Treatment (NPDES)	0.5

EFFECTS OF MERCURY ON METALLURGICAL EFFICIENCY

RENCO MINES LTD. in Zimbabwe recovers gold by cyanidation and CIP from an ore containing undersirable contaminants which interfere with the process. One of these (MENNE, 1984, personal communication) is bismuth which is believed to interfere with gold adsorption on carbon.

RENCO MINES LTD. adds 200g $HgCl_2$ to the pulp just before it reaches the first agitator. The $HgCl_2$ is added with the cyanide solution at the pump sump between the pulp pre-aeration tanks and the first leach agitator.

The 200g $HgCl_2$ dose was found to be critical. Any less than that, and gold recovery drops off. Any more does not help recovery but adds to expenses.

RENCO MINES LTD. made the fascinating observation that within minutes of being added, the mercury which was added in soluble form cannot be detected in the pulp solution. Of 200g $HgCl_2$ added in the circuit, only 50-70% can be found in the final tails.

Although the precise role of the mercury in gold leach and CIP enhancement is not yet understood, more information may be available from:

A second effect of mercury on gold leaching was referred to at a verbal presentation on gold recovery on the Witwatersrand by P.J.D. Lloyd (recollection only) who then was Research Director of the Chamber of Mines Research Laboratories in South Africa. He presented data which supported his view that gold dissolution by cyanide from Witwatersrand ores was inhibited by the presence of small amounts of mercury in the ore which necessitated a leach residence time long enough to dissolve the mercury before the last of the gold could be brought into solution. Information may be requested from:

DR. P.J.D. LLOYD
Managing Director
EMS Minerals
Post Office Box 585
Bedfordview - Johannesburg
South Africa

The above indicates that the addition of mercury in soluble form may enhance gold extraction, but mercury in mineral form may retard leach kinetics. It must be stated that the latter observation was presented more as a tentative hypothesis than a fact.

ENVIRONMENTAL SENSITIVITY - MERCURY

The biologically significant form of mercury is methyl mercury which is very much more toxic to aquatic organisms than inorganic mercury. According to JOHNELS, et al. (1967) and KAMPS, et al. (1972), the bulk of mercury found in fresh water fish occurs in the form of methyl mercury. Methyl mercury may also be demethylated by bacteria in sediments according to SPANGLER, et al (1973).

Methylation of mercury in the environment occurs by at least two mechanisms as described by WOOD, et al. (1968) and LADNER (1971).

Administrative guidelines for fish for human consumption promulgated by the U.S. Food and Drug Administration and the Canadian Food and Drug Directorate are set a 0.5 ug/g mercury in edible portions. There is no evidence according to ONTARIO (1979) that concentrations of 0.5 ug/g mercury in fish have any effect on the fish themselves. Concentrations of mercury in fish that have been killed by chronic exposure to methyl mercury ranged from 9.5 to 23.5 ug/g Hg according to ONTARIO (1979).

ONTARIO (1979) provides a table showing the results of a series of toxicity studies which demonstrate that most organic mercury compounds are more toxic than inorganic mercury salts.

ONTARIO (1979) concluded that fish-eating birds should be protected if the concentration of total mercury in whole fish does not exceed 0.5 ug/g.

Bioaccumulation of mercury occurs in many fish, bird, and other aquatic species, and some examples are cited in ONTARIO (1979).

With the exception of some of the most severe cases of mercury pollution, aqueous mercury concentrations, U.S. EPA (1980) and NRCC (1979), are generally well below levels which would affect the wellbeing of aquatic and marine life.

According to HEIT and FINGERMAN (1977), the method used by the EPA to extrapolate to the objective figure and the MPC provided an erroneous result. The figures must be erroneous considering the bountiful fish populations that thrive in water with significantly higher mercury background levels.

Crayfish are apparently particularly sensitive to mercury with LC-50 of 50 ug/l and LC-50 of 250-1,000 ug/l reported by two papers which is about 2,500 times higher than that reported by another worker.

The second most sensitive species listed by the U.S. EPA is Daphnia magna which was observed to have a 48-h LC-50 of 5 ug/l as Hg_2Cl_2 (data from BEISINGER and CHRISTENSEN (1972)). The LC-50 value found in their study is 2,940 times greater than the MPC.

Rainbow trout LC-50 value of 250 ug/l Hg is tested as Hg_2Cl_2 compared with 20 ug/l for methylmercuric chloride according to the U.S. EPA (1980). Rainbow trout are generally considered to be one of the most sensitive fish species, and their LC-50 values are 147,000 and 17,000 greater than the MPC which suggests that the MPC derived by the EPA (0.0017 ug/l) is unrealistic.

Several studies showed that no toxic effects were observed at the Environment Canada 0.1-0.2 ug/l total mercury objective level, but if 10-20% of the total mercury is in a methylated form, then bioaccumulation could potentially occur. However, methylmercuric chloride concentrations of less than 0.01 ug/l Hg do not appear to cause great increases in fish mercury concentrations over background levels.

It is concluded that in arid regions where metallurgical operations can be operated on a zero discharge basis, mercury is of less concern environmentally than worker exposure to mercury vapor derived from processing solutions containing levels of mercury that have become elevated due to water recycling.

In areas where effluents must be discharged, the Canadian MPC and objective for 24-hour average levels of mercury are reasonable, whereas the U.S. EPA objective is both unenforceable for lack of suitable analytical equipment and unrealistic, being not supported by environmental evidence.

Even if methods could be devised to detect mercury at the EPA objective levels, there are no known processes that can reliably remove mercury from water to the levels cited.

The U.S. EPA marine criteria for MPC and 24-hour average concentration (3.7 and 0.025 ug/l) are based on the results of toxicity tests rather than bioaccumulation potential. Industry observers find these limits scientifically defensible as opposed to the freshwater criteria.

Generally, the 24-hour average objective of 0.025 ug/l is close to typical background levels which suggests that little if any addition to the environment over a long period of time would be permitted although, of course, the oceans have such a large volume that they can tolerate significant additions before the average background level would be impacted.

The U.S. Marine MPC of 3.7 ug/l is in line with toxicity test results and should not be exceeded.

Ultimately, objectives may have to distinguish between methylated and inorganic mercury levels in effluents.

TREATMENT FOR MERCURY REMOVAL

1) Selective Leaching: Gold and Silver Cyanidation

The Bureau of Mines of the U.S. Dept. of the Interior has conducted research into the question of mercury in gold and silver cyanidation solutions and pulps. STAKER, et al. (1983) investigated selective extraction of Au and Ag from a

low-grade Au ore containing Hg. Gold and silver were extracted from the ore in cyanide slurries, and mercury extraction was suppressed with sodium or calcium sulfide. Maximum Au extraction and minimum Hg extraction were obtained using solutions containing 0.34 lb. NaCN/ton solution. Increasing the cyanide concentration increased the mercury extraction without increasing gold extraction. Mercury extraction from the ore was suppressed with 0.5-2.9 lb. CaS/lb. Hg in the ore. Gold to mercury ratios of 100:1 to 400:1 were obtained in the leach solution and on the activated carbon in a CIP circuit.

The above is potentially very significant, especially in low-grade ores in the western U.S.A. which may contain, for example, 2-3 g Au/t with 5-15 g Hg/t. During cyanidation, 10-30 percent of the mercury is extracted along with Au and Ag, and once in solution, mercury follows gold or silver through the process requiring extra precautions in the plant.

Mercury vapor may cause health hazards in the electrowinning, retorting, and carbon reactivation as well as carbon elution steps.

The USBM process to inhibit mercury dissolution is potentially useful in that mercury then stays in the tailing solids. However, careful scrutiny of the effect of CaS addition on cyanide consumption, gold and silver leach rates and efficiency, and adsorption characteristics on activated carbon would be necessary before employing this process.

Further information on progress in this direction and reference to commercial plants that employ this process would be available from:

W. L. STAKER
Salt Lake City Research Center
Bureau of Mines
U.S. Dept. of the Interior
Salt Lake City, UT 84108
(801) 524-6100

For applications where effluents must be discharged for water balance considerations, the question remains whether inhibition of mercury leaching would be adequate to keep mercury in effluents down to levels that would meet the regulatory requirements.

MERCURY REMOVAL FROM GOLD MILL SOLUTION/EFFLUENTS

In the course of this investigation, not one case was encountered where mercury is deliberately removed from a process solution stream or an effluent prior to discharge.

However, mercury is involuntarily recovered as a byproduct by the same extraction process as is used for gold and silver recovery. Examples of such operations are:

Zinc Precipitation - Retorting
Rosario Dominicana, Pueblo Viejo, Dominican Republic
Carlin Gold Mines, Carlin Nevada

Carbon-in-Pulp - Elution - Zinc Precipitation Retorting
Freeport Gold Company, Elko, Nevada

Carbon in Pulp - Elution - Electrowinning - Retorting of Steel Wool
Pinson Gold Mining Co., Winnemucca, Nevada
Getty Mercur Gold Co., Toelle, Utah

It is believed that Harrison B. Salisbury of the Dawson Metallurgical Laboratories has conducted research into ways to remove metals such as mercury and thallium from gold leach solutions.

DAWSON METALLURGICAL LABORATORIES
5217 Major Street
Murray, UT 84107
(801) 262-0922
Harrison B. Salisbury

Several other methods have been employed or are under development to remove mercury from industrial effluents, mostly on a smaller scale:

Precipitation
Ion Exchange
Chelating Compounds
The Devoe-Holbein Process
Coagulation
Reduction to Metallic Mercury and Filtration

PRECIPITATION

In industrial applications, sulfide addition to precipitate mercury sulfide is commonly used. This may be combined with flocculation and separation by gravity settling, filtration, or dissolved air flotation and is also the basis for keeping mercury out of cyanide solution in the leaching of gold and silver from mercury-rich ores. Sulfide precipitation was discussed by BOUVENG (Undated).

PATTERSON (1975) points out that for high initial mercury levels, sulfide precipitation will achieve 99.9% removal at alkaline pH but even with filtration or activated carbon polishing, minimum effluent mercury achievable by sulfide precipitation appears to be 10-20 ug/l. Most effective precipitation appears to be in the near neutral pH range as far as minimizing sulfide dosages according to PERRY (1974).

In addition to the lack of capability to reduce mercury below 10 ug/l, other drawbacks of this method include: 1) formation of soluble mercury sulfide complexes at high levels of excess sulfide; 2) the difficulty of monitoring excess sulfide levels; and 3) the problem of toxic sulfide residual in the treated effluent according to PERRY (1974).

Although the last two of these obstacles have now largely been overcome, the inability to reduce mercury levels to below 10-20 ug/l does not meet the EPA or Canadian ambient water criteria for protection of the environment.

SULFEX PROCESS

Mercury sulfide solubility in pure water is reported to be 1×10^{-21} by YELIGAR, et al. (1981) making it one of the least soluble sulfides. The Sulfex process, described by YELIGAR, et al. (1981) and SCOTT (Undated), employs an iron sulfide sludge bed in a sludge blanket-type clarifier to precipitate mercury and other metals. In this way, sulfide levels are maintained at a constant concentration regardless of the rate of sulfide demand.

The Sulfex process is patented and, together with the sludge blanket reactor clarifier, is offered by:

THE PERMUTIT CO., INC.
Post Office Box 355
E49 Midland Avenue
Paramus, NJ 07652
(201) 967-6000

To date, the Sulfex process has been employed primarily to treat metal finishing and plating effluents, and no operations are known where it is used to treat metallurgical plant effluents although in principle there are no reasons for it not to work.

BOLIDEN METALL, SKELLEFTHAM PLANT, SWEDEN

Sulfide precipitation is employed by BOLIDEN METALL at their Skellefteham plant in Sweden to remove arsenic at low pH 3.9 followed by filtration to remove the precipitate and lime addition to the filtrate to precipitate fluoride as CaF_2 followed by settling and decantation. This process is described by BLYTHE, et al. (1981) from which the following schematic diagram is taken showing that mercury in feed solution is dropped by sulfide precipitation from 3 ppm to 50 ppb and further to 10 ppb by lime addition and settling.

Typical residual metal concentrations obtained by full-scale test run (Boliden Metall).

SOURCE: BLYTHE, et al. (1981)

More information on this process, as well as the pitfalls to be guarded against when a complex solution is to be treated, is contained in the project summary by BLYTHE, et al. (1981). Additional insight may be possible from:

D. BHATTACHARYYA
Chemical Engineering Dept.
University of Kentucky
773 Anderson Hall
Lexington, KY 40506-0046
(606) 257-2798

According to BHATTACHARYYA (1985, personal communication), one of the problems is excessive cost at low pH when $SO_3^{=}$ is present because it consumes expensive sulfide reagent. A second problem is the efficient removal of finely divided sulfide precipitates. It is noted that at the low pH, mercury is removed only to 50 ppb and with subsequent

lime addition, to 10 ppb which more or less confirms the performance noted above for sulfide precipitation.

ION EXCHANGE

Most ion exchange treatments of inorganic mercury involve formation of a negatively charged mercuric chloride complex by adding chlorine to oxidize metallic mercury or chloride salts and removal of the mercuric chloride complex on an anion exchange resin. Most experience, according to PATTERSON (1975), has been with chloralkali plant wastes which contain high background chloride levels. There is some evidence, (PERRY, 1974, and GARDINER and MUNOZ, 1971), to indicate that the best ion exchange results are achieved in two stages with a roughing and a polishing step. Table 56 below from PATTERSON (1975) shows that anion exchange reduced mercury to 1 ppb in some cases.

Where chloride levels are low, cation exchange resins are effective. Although information on the cation exchange behavoir of mercury is scarce, Amberlite IRA-120 and Dowex-50W-X8 are both reported by ROESMER (1970) to be effective. Since then, of course, resin manufacturers have undoubtably developed improved resins for mercury removal, and it is recommended that sponsors get in touch with their local ion exchange salesmen for more information.

Resins that contain mercapto groups R-S-H such as polythiostyrene are highly specific for mercuric ions according to ROESMER (1970).

PATTERSON points out that regardless of whether anionic resins are used for mercuric chloride complex removal or cationic resins for mercuric ion removal, the best ion exchange treatment for inorganic mercury appears to yield an effluent with 1-5 ug/l. Most effective treatment results from two-stage treatment at neutral to slightly acidic pH.

Most available data relates to the treatment of inorganic mercury, and there is relatively little information on organic mercurials. However, efficient treatment of methyl mercury acetate has been reported with Dowex A-1 Chelate by MUZZARELLI and ISOLATI (1971) and Ionac SRXL resins by LAW (1971) whose paper is inserted below along with one by FREELAND, et al. (1974) who showed how polyethylamine-modified wool fibers can adsorb mercury as Hg^{2+} from solution. The process is said to be effective on 1 ppm Hg solutions, and effluents with only 0.02 ppm were achieved. Additional information on further progress in this field may be available from:

Australia

PATTERSON (1975) refers to the Osaka ion exchange process for mercury removal from acid solution which is available under license using an Osaka resin which achieves, according to GARDINER and MUNOZ (1971), levels as low as 5 ppb Hg. This reference may also include the address of the Osaka Company that markets this process and the resin.

A Swedish company (AKTIEBOLAG BILLINGSFORS-LANGED) has developed an ion exchange system which is similar in concept to the Osaka process. A strong base first stage exchanger is regenerable while the second stage polisher is not. Removal is as the mercuric chloride complex anion, thus requiring pretreatment of mercurous and organic mercury. More information is reported by CHEREMISINOFF and HABIB (1972) and ROSENZWEIG (1971).

WILMOTH, et al. (1979) tested lime neutralization, reverse osmosis, and ion exchange for their effectiveness in removing mg/l levels of ten trace elements from acid mine drainage under typical operating conditions. The contaminants were As, B, Cd, Cr, Cu, Hg, Ni, P, Se, and Zn. Treatment by lime neutralization was very effective in removing As, Cd, Ni, and Zn and ineffective for B removal. Dual-bed (strong acid-weak base) ion exchange was very effective in removing all the trace elements except P and B but including mercury.

Methyl Mercury and Inorganic Mercury Collection by a Selective Chelating Resin

Abstract. *A commercially available chelating resin selectively and quantitatively collects methyl mercuric and inorganic mercuric forms of mercury to the exclusion of all other metals studied, except the noble metals. Both forms of mercury can be collected from pH 1 to 9. Collected mercury is readily eluted with a slightly acid, 5 percent solution of thiourea, and the resin can be reused for many cycles. Selectivity, pH effects, capacity, and elution characteristics of the resin are described. A resin-loaded paper composed of 50 percent resin and 50 percent cellulose shows properties similar to those of the loose resin.*

The purpose of this report is to summarize available tests on a chelating resin, Ionac SRXL (*1*), which should provide new opportunities for analysis and for recovery of mercury from industrial and natural aqueous solutions. Previous studies have shown that the resin is highly selective for gold and platinum metals, but its usefulness for mercury had not been considered (*2–4*). My results indicate that the resin has a high affinity for dissolved mercury in both the methyl mercury and the inorganic forms.

Kuster and Schmuckler, original developers of the resin (*2*), explain the selectivity for noble metals by stating that it will ". . . bind only ions with the d^8 electronic configuration forming square planar complexes. . . ." They further explain that the resin has redox properties because of double bonds, enabling it to collect a species such as Pt^{4+} which is reduced to the Pt^{2+} and then bound as a square planar complex. The mechanism for Hg^{2+} and CH_3Hg^+ collection has yet to be determined.

The properties of SRXL resin were studied in two ways. Data were obtained with resin as received from the manufacturer and with resin-loaded paper, consisting of 50 percent SRXL resin (−325 mesh) and 50 percent cellulose (*4*). Comparisons were made between the resin behavior in a column and its behavior in the resin paper. All solutions were prepared with reagent-grade chemicals, and tracer studies were performed with the ^{203}Hg radioactive isotope and a NaI(Tl) detector.

Selective collection of noble metals, especially gold, from solutions containing high concentrations of more common metals has been reported (*2–4*). I have found also that the resin quantitatively collects dissolved mercury as methyl mercury or as inorganic mercury from solutions of high common metal concentration. A column of resin, 30 by 15 mm, quantitatively collected 100 μg of Hg^{2+} from 250 ml of chloride solutions of iron, nickel, copper, and zinc in amounts up to 10 g/liter. Radioactive ^{203}Hg was used to determine the completeness of collection (Table 1).

Selectivity tests for mercury in the CH_3HgCl, $HgCl_2$, and $Hg(NO_3)_2$ forms were conducted by filtering solutions containing a mercury salt mixed with various metals through paper disks (3.5 cm in diameter) containing SRXL resin; the solution was passed six times through each disk. The disks were rinsed with dilute HCl solution, dried, and analyzed by fluorescent x-ray spectrography. From solutions containing Fe^{3+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, and Hg^{2+} or CH_3Hg^+, only the mercury was detected on the disks; the instrument conditions were sensitive to less than 5 μg for any one of the metals. Neutron activation analysis of SRXL paper disks which were used to collect gold from solutions containing nitrate or chloride salts of metals failed to show any common metal collection (*4*).

Comparisons with another resin, Chelex 100, reported to have a high affinity for Hg^{2+}, show that the Chelex 100 resin fails to collect the methyl mercury form although it does quantitatively collect Hg^{2+}. A paper specially prepared (H. Reeve Angel & Co.) with the Chelex 100 resin, was compared chromatographically with the SRXL

Table 1. Mercury ion (Hg^{2+}) collection from solutions of high metal concentration.

Conc. of Fe, Ni, Cu, and Zn mixture (g/liter)	^{203}Hg (count/min)*			Hg collected (%)
	Before	After	Background

18 June 1971; revised 24 August 1971

paper. Metal mixtures including Hg^{2+} and CH_3Hg^+ were placed on both papers and developed under identical conditions. The SRXL paper showed complete separation of all metals examined (Fe^{3+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Pb^{2+}) from the Hg^{2+} and CH_3Hg^+ spot, which always had an R_f value of 0. The common metals showed no tendency to be retained by the paper. The Chelex 100 paper showed some affinity for most of the metals. Some spreading of the Hg^{2+} was also noticed. This comparison emphasizes the fact that the SRXL resin has the ability to discriminate between mercury and base metals instead of merely exhibiting varying degrees of affinity for the different ions as is more commonly observed in ion exchange.

The effect of *p*H on the collection of mercuric chloride, mercuric nitrate, and dissolved methyl mercury by the resin and the resin paper was examined over the *p*H range of 0.1 to 9. The results (Fig. 1) suggest the possibility of separating the forms of mercury in solution by *p*H adjustment. The trends and not the magnitudes are significant because different experimental procedures were necessary depending on whether the resin or the paper was used. Collection times were restricted to avoid quantitative collection as the purpose of this study was to observe differences in diffusion and absorption kinetics.

For the loose resin (Fig. 1A), a 200-ml solution, adjusted to the desired *p*H with dilute HCl and NaOH and containing ^{203}Hg radioactive tracer and 1000 μg of Hg^{2+}, or $CH_3{}^{203}Hg^+$ tracer and 990 μg of Hg as CH_3Hg^+, was shaken with 0.33 g of resin on a mechanical shaker for 2 hours. Portions (3 ml) were taken for the determination of radioactivity before resin addition and after shaking, in each case, to determine the amount of mercury collected by the resin. Although mercury is collected at *p*H > 7, use of the resin is probably best confined to *p*H < 7 as recommended by Koster and Schmuckler (*2*). The lowest collection of inorganic mercury is at *p*H 6. One liter of a *p*H 6 solution containing ^{203}Hg tracer and 100 ppm of Hg^{2+} as the chloride was prepared and passed through a small column (1 by 1.5 cm; 0.75 g) of the resin. The effluent from the column was periodically checked for ^{203}Hg activity. After about 600 ml of the solution had passed through the resin at an initial flow rate of 3 ml/min, a small amount (about 2 percent) of

Fig. 1. Effect of *p*H on the collection of inorganic mercury (○) and dissolved methyl mercury (△), by SRXL resin (A) and SRXL resin-loaded paper (B).

mercury tracer began to come through the column. When the flow rate was reduced to approximately 1.5 ml/min, the mercury collection was again quantitative, and no further escape of mercury from the column was observed for the remainder of the 1000 ml of solution. These observations indicate that the total capacity of the resin is probably the same at *p*H 6 as at the lower *p*H values, but the rate of collection of Hg^{2+} is slower at *p*H 6. Therefore, a slower flow rate will be all that is required for quantitative recovery of inorganic mercury at this *p*H.

For the SRXL paper (Fig. 1B), small disks (1.3 cm in diameter) of the paper were suspended by thread for 24 hours in solutions of various *p*H, each solution containing 1000 μg of Hg as $HgCl_2$ or 930 μg of Hg as the methyl mercuric chloride. The disks were dried, and the mercury content was determined by fluorescent x-ray spectrography.

The sudden decrease in collection of the inorganic mercury at *p*H 6 is apparently the result of a reduction-precipitation reaction occurring on the surface of the suspended disks. The surface of the paper disk turns dark, and a white precipitate forms in the solution around the disk, suggesting the reduction of the Hg^{2+} to Hg^0 and Hg_2^{2+} followed by precipitation. An essentially identical curve of the effect of *p*H on behavior, with darkening of the disks and formation of a white precipitate, is also observed in the collection of $Hg(NO_3)_2$ from nitrate solutions containing no chlorides. Filtering solutions of *p*H 6 or greater through SRXL resin-loaded paper results in quantitative recovery of the inorganic mercury. No precipitate formation or darkening of the disks was noticed in the solutions containing the methyl mercury.

The capacity of the SRXL resin for Hg^{2+} was determined by shaking 1-g portions of the resin with chloride solutions at *p*H 1.5 containing 2 g of $HgCl_2$ and 10 μc of ^{203}Hg. Portions were taken at intervals for the determination of radioactivity until no further loss of tracer from solution was observed. The capacity of the resin under these conditions was 540 to 550 mg of Hg^{2+} per gram of dry resin. This compares well with the 488 mg per gram of dry resin found by Koster and Schmuckler for Pt^{4+} (*2*).

A 5 percent aqueous solution of thiourea containing 5 ml of hydrochloric acid per liter will elute gold and platinum metals from the resin, permitting its reuse for many cycles (*3*), therefore this eluent was investigated for the removal of mercury from the SRXL resin. A series of eight cycles of mercury collection and elution were performed with the same 2-g portion of resin. For each cycle, mercury was collected from 100 ml of solution containing ^{203}Hg tracer, and each cycle contained the same amount or more mercury than the one preceding. The 100-ml volumes contained from 100 μg to 1 g of Hg. Tracer activity of 3-ml portions of each effluent showed that the collection was 100 percent at all concentrations. Mercury was then eluted from the resin with 10-ml portions of the 5 percent thiourea solution. More than 90 percent of the mercury was removed with the first 10 ml of eluent in each case, and elution was essentially complete after passing 30 ml through the resin. A rate of approximately 3 ml/min was used for the elution and the collection. After elution of the mercury, the excess thiourea was washed from the resin with distilled water, and the next 100 ml of solution were passed through the resin, starting the next cycle.

Thus the ability to selectively and quantitatively collect the highly toxic methyl mercury as well as inorganic mercuric salts, and the ability to be reused for many cycles, make this resin a very promising tool for attacking both the analytical and the industrial problems of mercury pollution.

Adsorption of Mercury from Aqueous Solutions by Polyethylenimine-Modified Wool Fibers

Graeme N. Freeland, Ronald M. Hoskinsen,* and Robert J. Mayfield

CSIRO, Division of Textile Industry, P.O. Box 21, Belmont, Victoria, 3216, Australia

■ When used in a packed column or a standing bath, polyethylenimine-modified wool (PEI-wool) had a substantially greater ability to adsorb mercury (Hg^2) from aqueous solution than unmodified keratin. A capacity of 3.3 meq/g was achieved within 30 min using solutions of 1000 ppm (Hg^2). Sorption from liquours passing through a column was rapid and effective at the 1-ppm level. The sorbed mercury was readily desorbed and the PEI-wool used repeatedly.

There have been several recent reports of the ability of protein fibers to adsorb mercury from aqueous solution (*1–4*), and the possibility of using them in effluent purification processes or for clinical purposes (*5*) has been discussed. Likewise, amine-modified cotton could adsorb mercury from solutions (*6, 7*). Here we report that the adsorptive capacity of wool for mercury (Hg^2) is substantially increased by polymerization of ethylenimine onto the fibers.

Experimental

PEI-Wool. Commercially scoured 64's quality Australian merino wool fibers (40 grams) were immersed (2 hr) in a 0.2% solution of ferrous ammonium sulfate (800 ml) and then squeezed before allowing to dry (48 hr) at 20°C. To the wool was added 0.25% hydrogen peroxide solution (600 ml) and ethylenimine (30 ml) (*8*). [Because of potential hazards from exposure to ethylenimine, it has been recommended (*9*) that protective gloves and goggles be used and that all operations be performed in a fume hood.] The fibers were heated (19 hr) at 50°C under nitrogen, rinsed under running tap water (2 hr), dried as before, and chopped to 1–3 mm lengths in a rotary mill. The uptake of ethylenimine (as bound PEI) was 10% w/w.

PEI-Reduced Wool. Unmodified wool (10 grams) was chemically reduced with 0.5M thioglycollic acid (300 ml) at 50°C for 3 hr, washed with distilled water, dried (100°C, 5 min), and converted to PEI-reduced wool as above. The uptake of ethylenimine (as bound PEI) was 20.2% (w/w).

Adsorption onto Columns of Chopped Wool Fibers. The wool (5 grams) was wet out in water containing 0.01% Antarox C0630 (a polyoxyethylated nonylphenol, GAF Corp.) and the resulting slurry poured into a glass column fitted with a porous plug and stopcock. When the fibers had settled they were equilibrated with solutions at the pH of the test solutions. The test solutions contained 1000 ppm Hg^2 (as $HgCl_2$ or a combination of $HgCl_2$–NaCl, Table I) and adjusted to various pH values with NaOH or HCl. Test solutions were admitted at the rate of one bed volume/min. The column effluent was collected in fractions and their mercury concentration measured.

Adsorption onto Wool in Standing Bath. The wool (5 grams) was stirred in a glass beaker with a solution (1 liter) adjusted to the required pH, containing 1000 ppm Hg^2 (as $HgCl_2$ or $HgCl_2$–NaCl, Table I) for prescribed periods.

Capacity of Wool Fiber Beds. Here the capacity of the beds has been expressed as milliequivalents of mercury per gram of wool (meq/g). For adsorption onto columns it was the amount of mercury adsorbed by the bed when its concentration in the column effluent reached 1% of the influent concentration. For adsorption onto wool in standing baths it was the amount adsorbed from the liquors after the prescribed period, and the value was calculated from the decrease in mercury concentration of the bath liquor. All adsorption measurements were made at 20°C.

Mercury Analysis. This was by atomic absorption spectrophotometry. Separate procedures used for solutions containing 1–1000 ppm (*10*) and up to 1 ppm Hg^2 (*11*) were essentially as described.

Results and Discussion

PEI-Wool. Protein fibers will bind approximately 1% of polyethylenimine irreversibly (*12*). This quantity will increase slightly if the fibers are pretreated with chlorine. By polymerization of ethylenimine monomer onto wool fibers, as reported here, irreversible binding of 10–20% PEI can be achieved. It is not known whether the PEI-wool composite so formed contains the PEI as a physically occluded or chemically grafted component. In the present work, wool treated by the last method has been used as packed beds in columns and in stirred standing baths to examine its potential in both continuous and batchwise mercury recovery processes.

Table I shows that maximum adsorption occurred in standing baths where, within 30 min, equilibrium was established. The capacity of 3.3 meq/g is of the same order as that of many granular ion exchangers. Even in solutions containing 10% NaCl, the adsorption of 1 meq Hg^2/g was still significant and may indicate that PEI-wool could

[a] S with a numerical subscript refers to adsorption in a standing bath for the indicated period (min); C refers to a column adsorption. [b] From (*1*).

have practical advantages in adsorbing mercury from electrolyte solutions (*13*).

In column adsorption tests, where the contact time was 1 min, the capacity was lowered slightly to 2.4 meq Hg^2/g at pH 7, indicating that adsorption was a rapid process. Sorbed mercury was quantitatively recovered by extracting the PEI-wool with *N* HCl (50°C, 15 min) or with citric acid solution (1%, pH2, 40°C, 15 min). The wool that was stripped in this way could be reused, an adsorption capacity of 2 meq/g persisting after 15 cycles.

Adsorption onto columns was effective when low concentrations of mercury were used. When 500-bed volumes of liquor containing 1 ppm Hg^2 (pH 6) were passed through the column (1 bed vol/min), the concentration in the effluent did not exceed 0.02 ppm. Greater efficiency could be expected from longer contact times in the column.

When we consider the pH range 2–7, we note that modification of wool with PEI changes the pH of maximum adsorption from 2 to 7; corresponding differences in the adsorption mechanisms might be inferred. Probably, at pH 2, the association of protonated amino groups with anionic mercuric complexes such as $HgCl_3^-$ or $HgCl_4^{2-}$ occurs (*1*). At pH 7, the adsorption probably involves chelation of Hg^2 with ligands located in both the PEI (*14*) and the wool.

PEI-wool appears to have a mercury adsorbing capacity exceeding cross-linked PEI-cotton (*6*) by a factor of 100. Although strict comparisons have not been made its rate of adsorbing mercury seems substantially greater than that reported for the modified cotton (*7*).

PEI-Reduced Wool. Ethylenimine was polymerized onto thioglycollate-reduced wool in the expectation that the chemically modified fibers, released from the restraint of protein disulfide bonds, would swell more readily in aqueous media. An increased PEI add-on and correspondingly improved mercury adsorption might then have resulted.

Practically, the amount of PEI formed in reduced wool was double that formed in native wool. Only minor increases were observed in the mercury-adsorbing capacity of PEI-reduced wool, consequently no advantage can be seen in using wool in the reduced form.

Removal of Mercury from Aqueous Solutions by *N*-(2-Aminoethyl)aminodeoxycellulose Cotton

Stephen L. Snyder and Tyrone L. Vigo

Southern Regional Research Center, Agricultural Research Service, U.S. Department of Agriculture, New Orleans, La. 70179

■ *N*-(2-Aminoethyl)aminodeoxycellulose cotton (AEAC) was prepared in yarn form by reaction of ethylenediamine with chlorodeoxycellulose. The adsorption of mercuric ion by AEAC (degree of substitution 0.4) was studied over a wide range of concentrations. In the concentration range 0.5–43 g/l., the adsorption of mercuric chloride follows the Freundlich relationship, $\log_{10} x = 0.21 \log_{10} C + 2.7$, where x is the mg of mercuric chloride bound per gram of AEAC and C is the residual concentration in g/l. At concentrations in the range of 3.1–0.6 ppm, 100 mg of AEAC removed about 90% of the mercury present in 200 ml of solution, in a single equilibration. The results of this study suggest the possible use of AEAC as an agent for the collection of mercury in industrial processes.

The possibility of employing ion exchange or chelating resins as a means of removing heavy metal ions from solution has been explored by a number of workers (*1–5*). However, cost considerations have prohibited the widespread application of this technique on an industrial scale. A possible solution to the cost problem might be to use naturally occurring polymers or agricultural by-products as the basis for the exchange resin. In this regard, Friedman and coworkers (*6, 7*) have shown that mercuric ion is bound in large amounts by certain agricultural byproducts and polyamine derivatives.

This investigation concerns the use of cotton cellulose as the insoluble support matrix; however, the same techniques could be readily applied to other celluloses or synthetic polyalcohols. In the study reported here, we have attached an ethylenediamine group to the anhydroglucose unit of the cellulose backbone via chlorodeoxycellulose (CDC) cotton yarn to give *N*-(2-aminoethyl)aminocellulose cotton (AEAC). AEAC very efficiently adsorbs mercury over a broad range of concentrations. Suprisingly, we observed that at very low concentrations (approximately 100 ppb), untreated cotton yarn also removes significant amounts of mercury. This adsorption may be due to carboxyl end groups and trace materials present in native cotton.

Experimental

Materials. Cotton was loose twist 12/3 (tex-151) Pima kier-boiled yarn unless otherwise specified. The phosphorus oxychloride ($POCl_3$), dimethylformamide (DMF), and

CHELATING COMPOUNDS - INSOLUBLE STARCH XANTHATE

Recently a company in Texas, POLLUTION TECHNOLOGY SYSTEMS, INC., has offered a process and a chelating organic product which removes metals including mercury from solution.

The product, DX-2000, is a buffered forty percent active organic material that effectively precipitates complexed or chelated cationic heavy metals from difficult to treat process waters. The vendors claim that the product is effective over a pH range of 3 to 11. Residual heavy metals are claimed to usually be well below local, state, and EPA-NPDES discharge limit permit requirements.

DX-2000 is claimed to be effective in removing metals also in the presence of complexing agents which would normally interfere with most other removal processes. The metal-DX-2000 sludge cake containing 40% solids is claimed to be more stable than metal hydroxide sludges.

Dosages of DX-2000 for metal removal vary from metal to metal as the loading ability of a liter of DX-2000 varies from metal to metal. For example, Mn^{+2} loads 77 g per liter of DX-2000 whereas gold loads to 550 g Au^{+1}, and silver loads to 300 g Ag^{+1} per liter of DX-2000. Mercury loads to 280 g Hg^{+2} per liter of DX-2000.

The manufacturer-vendor does not make claims regarding the level of mercury that can be achieved using DX-2000. In a pamphlet by the same vendor describing the use of insoluble starch xanthate, it is claimed that mercury levels were reduced to 0.7 and 1.0 ppb in two test solutions.

It is not known what the nature of the DX-2000 product is although the same vendor is known also to manufacture insoluble starch xanthate based on technology developed by the U.S. Dept. of Agriculture.

NORTHERN REGIONAL RESEARCH LABORATORY

U.S. Dept. of Agriculture
1815 North University
Peoria, IL 61604
(309) 685-4011
Robert E. Wing

The insoluble starch xanthate is claimed to have removed mercury from 100 ppm to 1 ppb in one case and from a second solution containing 10 ppm to 0.7 ppb Hg.

The development of insoluble starch xanthate for heavy metal removal (including mercury) has been described by SWANSON, et al. (1973), WING, et al. (1974), GREENBERG and WING (1983), and WING (1983).

The vendor does not release much detail about how its process works as they wish to sell consulting and engineering services as well as product. More information can be obtained from:

IKEBE (1974) of SUMITOMO CHEMICAL CO. LTD., Japan, described a process whereby heavy metal ions, especially Cu^{2+} and Hg^{2+}, are sequestered with a dialkyldithiocarbamic acid and are treated with NaOH and Na_2S to produce a scum of CuS and PbS separating the sulfide scum by either precipitation or flotation and regenerating the dialkyldithiocarbamate ion which is then recycled "quantitatively." The use of NaOH in this process improves the efficiency of separation by preventing the formation of colloidal CuS. Thus, $Cu[S(S)CNEt_2]_2$ was suspended in one litre water, and two equivalents of NaOH was added and stirred. One mole Na_2S/l was added, and the CuS formed was removed by precipitation.

When one equiv. of Na_2S was added, approximately 100% of the $NaS(S)CNEt_2$ was recovered. The light yellow liquor recovered had a pH of 12.8 and contained only 1-2 ppm Cu. When NaOH was not used, the recovered $NaS(S)CNEt_2$ contained about 35% of the colloidal CuS in suspension.

DEVOE-HOLBEIN

Devoe-Holbein has also developed a metal removing process which relies on a "composition" or solid adsorbent to precipitate and remove metals. Examples are cited in their literature in which mercury was removed from 12.0 ppm to 4.8 ppb in one case and from 120 ppm Hg to 1.2 ppb in another. A schematic flowsheet for a process employing Devoe-Holvein compositions has been developed and an association formed with an engineering company to develop a practical process.

More information can be requested from:

Telex: 05-821538
Bruce Holbein

Devoe-Holbein has not released data on the costs of the process or their "compositions." It was stated that in experimental quantities, the composition would be expensive. Prices

would be much, much lower if the product were in such demand as to justify mass production.

COAGULATION TREATMENT

Removal of mercury by coagulation has been reported for a variety of mercury-containing wastewaters. Coagulants employed include aluminum sulfate (alum), iron salts, and lime. The process has been applied successfully to both organic and inorganic mercury. In pilot plant tests of alum and iron treatment of inorganic and methyl mercury, inorganic mercury was removed effectively only by iron while neither coagulant provided effective methyl mercury removal according to O'CONNOR (1974).

Treatment data for alum and iron coagulation are summarized in the following table . Effluent levels of mercury achieved by alum treatment range from 1.5-102 mg/l and by iron treatment from 0.5-12.8 mg/l. Iron appears to be better than alum for the purpose achieving a lower effluent limit.

ACTIVATED CARBON

The effectiveness of carbon treatment is dependent on several factors according to PATTERSON (1975). These include the chemical form of mercury in solution, concentration of mercury, dosage and type of activated carbon, as well as contact period. Increasing carbon dosage and contact times improves removal of both inorganic and organic mercury as would be expected and as described by LOGSDON and SYMONS (1973). Organic mercury is more effectively removed than inorganic mercury, and a

review of available treatment data by PATTERSON (1975) and shown below in tabular form indicates that the highest percentage removals (85-90%) result from carbon treatment of more concentrated mercury solutions. However, the lowest effluent mercury results from the treatment of lower initial mercury concentrations although the relative efficiency is less. Thus, carbon treatment of initial mercury levels of below 1 mg/l yields an efficiency of removal of less than 70%, but an effluent mercury of less than 0.25 mg/l. Carbon treatment of initial mercury of 10-100 mg/l yields 90 or more percent efficiency but effluent levels of 1-10 mg/l.

REDUCTION PROCESSES

Inorganic ionic mercury can be converted to the metallic form by reduction and separation by filtration or other solids separation methods. Several reducing agents are available including aluminum, zinc, hydrazine, stannous chloride, and sodium borohydride. PATTERSON (1975) references the use of reductive processes to treat solutions with initial mercury concentrations of 1.8-26 ppm Hg which resulted in final mercury levels in the effluents of 5-830 ug Hg/l.

In gold and silver recovery processes using the Merrill-Crowe process (zinc precipitation), mercury will be reduced as well as gold and silver and ends up in the zinc precipitate. If there is enough mercury present, this necessitates an additional step to retort the zinc precipitated metals to remove the mercury before the gold and silver can be smelted to a dore.

The data provided by PATTERSON indicates that in order to achieve mercury levels below 100 g/l, the use of reductants would have to be supplemented by a second polishing step by one of the other treatment steps discussed in this chapter. For example, where gold plant effluents are treated by ferrous sulfide addition and settling to remove cyanide, chances are excellent that mercury will also be precipitated as a sulfide. If carbon columns are used to recover incremental gold from effluents or recirculating solutions, the likelihood of further mercury removal is also excellent by carbon adsorption. If, in future, anionic ion exchange resins are used to recover gold as a cyanide complex, then possibly a pretreatment with chlorine to destroy cyanide will render the mercury in the chloride complex form suitable for loading onto the resin as well, or mercury may load as the anionic mercury cyanide complex.

A full-scale commercial process based on the reduction of mercury by sodium borohydride is marketed as the Ventron process and is described by CHEREMISINOFF and HABIB (1972) and ROSENZWEIG (1971).

ADSORPTION PROCESSES

RANDALL (1974) tested the adsorptive properties of a wide range of agricultural wastes for the removal of toxic metal cations from synthetic solutions as well as mining and industrial effluent streams with a view to recovering metal values. Several of these wastes were reported to remove metals effectively to "below the levels prescribed by local or federal standards." Rate, selectivity, and capacity of the agricultural substrates for heavy metal cations were measured in the laboratory, and the authors claim very effective

removal of Pb^{2+}, Hg^{2+}, Cu^{2+}, Cd^{2+}, and Zn^{2+}. As with several of the processes mentioned above, this approach was not observed in commercial application although it may be worth further evaluation.

OTHER TECHNOLOGY

PATTERSON (1975) refers to a variety of other processes that are mentioned in the literature. These include solvent extraction with high molecular weight amines, the use of silicon alloys for reduction to elemental mercury (McKAVENEY, 1972), removal by insoluble starch xanthate-cationic polymer complexation (SWANSON, 1973; WINZ, et al. 1974), adsorption onto ground rubber and onto wool at sulfhydryl sites (FREELAND, et al., 1974).

Several of these processes appear promising yet in the course of this investigation, none were found in commercial application ten years after they were announced. It is emphasized that such experimental processes require considerable further development and pilot-scale testing before they could be considered suitable for commercial-scale application.

CONCLUSIONS

There are many treatment technologies available for mercury control. The more effective are summarized in the following table which was assembled by PATTERSON (1975). Among the processes listed, ion exchange, iron or alum coagulation, and activated carbon adsorption have the capability to reduce mercury below 10 ug/l, but the effects of cyanide on performance needs to be determined. The trip report on COTTER CORP.'s Schwarzwalder Mine in Appendix I describes an innovative new ion exchange process that reduces uranium and base metals to extremely low levels. Possibly this system would make further improvement possible in the performance of IX for mercury removal.

Conventional precipitation systems employing sulfide and flocculating aids seem capable of achieving mercury levels of 10-20 ug/l. However, RANDOL INTERNATIONAL suggests that combining the HDS process with ferrous sulfide or Na_2S addition may make it possbile to improve this when treating acid solutions.

Other methods, particularly the reduction process for small-scale use, are capable of producing very low-effluent concentrations of mercury. Many of these methods have not been tested in full-scale operation.

By Richard T. McNerney

Analysis of mercury using a gold film detector

ATOMIC ABSORPTION (AA) flameless spectrophotometry is currently the most commonly used method for the determination of mercury in liquid matrices. However, serious limitations of the technique, including inconsistencies in the liquid calibration standard, interferences, and poor reproducibility, have raised questions regarding the accuracy of the AA method. The thin gold film (gf) technique described in this paper overcomes these limitations and at the same time reduces the complexity of mercury analysis.

The detection of elemental mercury vapor by thin gf sensors is a technique developed and patented by the Jerome Instrument Corporation.[1] The adsorption of elemental mercury vapor on a gold film approximately 200 Å in thickness produces a pronounced resistance change in the film; this resistance change is linear in the range of 1–100 ng of mercury.[2]

Dedicated, portable instruments utilizing the thin gf sensor for the analysis of mercury in dry soils by direct combustion and in air by direct sampling have been in use for several years. Recently a thin gf mercury analyzer and sample delivery system, the Jerome Instrument model 511, has been designed for the analysis of mercury in liquid matrices.

Mercury vapor, released in an air stream from aqueous solutions using wet-chemical procedures described later, is drawn into the instrument by an internal pump. The elemental mercury passes over, and is adsorbed and integrated by, the thin gf sensor. This integrated electronic signal is converted by a microprocessor to the mass of mercury per unit volume of sample. Data presentation by direct digital readout is in nanograms of mercury. Saturation of the sensor occurs after 500 ng of mercury has been accumulated; full sensitivity is reestablished in 10 min by thermal desorption of the mercury from the sensor.

Mercury concentrations normally found in liquid matrices such as water, urine, and blood are in the low nanograms per milliliter range. But quantitative analysis depends on a system that is not only sensitive to mercury, but is also selective for the element. A serious limitation to the AA technique for mercury analysis is the presence of interfering substances such as H_2O, SO_2, O_3, and a variety of organic and inorganic compounds.[3–6] The complexity of the techniques developed for the preparation and analysis of liquid samples for mercury are a result of the efforts to overcome these interferences.

The thin gf sensor's specificity for mercury eliminates most interferences common to the AA technique,[7,8] and its design has resulted in significant improvements in signal reproducibility, calibration technique, and full-range linear response. The glassware system for sample preparation and delivery eliminates potential mercury loss from the sample. Microprocessor control reduces the complexity of the instrument's operation to a single manual control. With a minimum detection limit of 1.0 ng of mercury, the volume of sample necessary for analysis is usually less than 5 mL. Thus, the amount of reagent used in sample preparation is significantly reduced, minimizing the reagent blank. The system is field portable for on-site analysis where degradation of the sample due to transportation and long storage is a concern.[8]

Calibration

The thin gf technique determines the mass of mercury per unit volume of sample; thus, calibration can be performed using the most basic standard possible—the vapor pressure of mercury.[9] A small drop of liquid mercury in a closed container, e.g., a 300-mL polyethylene bottle, will saturate the enclosed air at a value which depends only on temperature. The effect of total pressure on the vapor pressure of mercury is negligible. The relationship of mercury concentration in ng/cm³ to temperature is shown in *Table 1*.

With the saturated mercury vapor maintained at a constant temperature, a known mass of elemental mercury is injected directly into the flow path of the thin gf sensor using a gas-tight syringe. The ana-

Figure 2 *Aqueous vs vapor standardization.*

lyzer responds linearly to a series of mercury vapor standards. After a 10-min film heat which thermally desorbs the accumulated mercury, sensitivity and full range linearity are restored. This is illustrated in *Figure 1*.

Figure 2 shows the excellent correlation that exists between the vapor phase and aqueous mercury standards. However, the correlation will suffer due to the instability of liquid standards and the errors that occur in the preparation of the stock and working liquid solutions.

An accurate vapor standard depends on maintenance of the calibration vessel at a constant temperature and withdrawal of a precise volume of the standard. Dilution is not necessary since the vapor standard is within the working range of the instrument. Oxidation of the mercury droplet, which could reduce the vapor pressure of mercury, is prevented by periodic light shaking of the calibration vessel.

However, liquid standards for mercury, both stock and working solutions, have shown varying degrees of instability. For example, a 1000-ppm ± 1% mercury reference solution (certified AA standard), with an expiration date sixteen months from the date of initial use, over a period of four months decreased in mercury concentration by more than 20%. Working solutions of 20 ppb prepared from a liquid standard according to well-documented procedures will, when shaken slightly, evolve elemental mercury in significant quantities in the head space

above the solution. As a result, the linear correlation that is observed for the vapor versus aqueous standards immediately after preparation of the working solution can deteriorate significantly over several hours.

Mercury reference standards for mercury in solution are prepared by weighing out and dissolving crystals of $HgCl_2$ in distilled water that has been slightly acidified. The significant sources of error in this technique are the weighing of the $HgCl_2$, the purity of the $HgCl_2$, and the possible mercury contamination of the labware used. The solution is then subject to decomposition as noted previously.

Whether the reference standard is purchased in liquid form or prepared by dissolving $HgCl_2$ in distilled water, concentrated stock solution must be diluted from one million ng/mL to a working solution containing 20 to 100 ng/mL. Possible sources of error include the dilution process itself, and the possibility exists for mercury contamination or the loss of mercury to the glassware used in the dilution process.

Inteferences

Independent studies regarding the lack of response of the thin gf sensors to interferences common to AA have been published,[6,7] and some of the results are shown in *Table 2*. Murphy[6] considers the chemicals listed in Table 2 to be some typical examples of the troublesome types of samples that cause interference in the direct determination of mercury. The gold film system permits each of these samples to be analyzed directly and accurately without interferences from possible gaseous emissions that may be interpreted as mercury.

SO_2, ozone, organic and inorganic compounds, and fine particulates do not cause a response of the thin gf sensor; the gf sensor also does not respond to water vapor. As a result, drying agents such as magnesium perchlorate, which have been shown to be a negative interference with AA instruments, are not necessary with the gold film detector.[4]

Also noteworthy is that several wet chemical preparations include two or three additional reagents to eliminate potential AA interferences such as sulfides and chlorine. The lack of response by the gf method to these interferences can thus simplify the chemical preparation of a sample.

Reproducibility, precision, and accuracy

In AA analysis, reproducibility is dependent on the rate at which mercury is liberated from solution. Factors which affect this rate of release are pump rate, bubbler characteristics, sample matrix, sample volume, and relative strength of the reducing agent.[10,11]

In contrast, the integration of the mercury signal by the thin gf sensor makes the analyzer relatively independent of the factors which affect the rate of release.

The precision of the analyzer was demonstrated in an independent evaluation comparing the model 511 to a flameless AA spectrophotometer.[12] Forty-five urine samples were analyzed in triplicate with each instrument. The sample size analyzed by the gold film detector was 0.2 mL, as compared to a 2.0-mL sample required by the AA spectrophotometer. The results listed in *Table 3* gave a coefficient of correlation of 0.985 between the two instruments. The relative standard deviation of the results

obtained with the gold film detector was 2.4%, as compared to 6.8% for the AA instrument.

As mentioned previously, the linear range of the gold film detector is 1 to 100 ng with gf saturation occurring at 500 ng. At levels above 100 ng, the microprocessor automatically corrects for nonlinear response. A series of 2-mL injections of mercury-saturated vapor gave responses of between 21 and 26 ng, totaling 470 ng, 94% of film saturation. The vapor reference was maintained at 18.5°C. The RSD for this set of data was 5.7%.

Suggested analytical procedure for mercury in solution

Gold film technology coupled with microprocessor control and an improved glassware delivery system have enhanced the quantitative analysis of mercury in liquid matrices, while at the same time reducing its complexity.

An illustration of this is the recommended procedure for the preparation and subsequent analysis of mercury in urine. The sample preparation is a modification of the American Congress of Government Industrial Hygienists (ACGIH) method No. 165, published in the ACGIH *Analytical Methods Manual*.

It is extremely important to immerse new glassware in concentrated HNO_3 for at least 8 hr. After this initial mercury decontamination, normal rinsing in acid is required to ensure mercury-free glassware. To prevent contamination of the stored glassware, continuous immersion in distilled water is recommended.

It is important that the sample preparation glassware *never* come into contact with reducing agents such as stannous chloride or sodium borohydride, because mercury in the sample can be lost due to carry-over of these reagents.

The detailed procedure is as follows: Under a fume-hood, add 1 mL of concentrated HNO_3 to a 30-mL Pyrex test tube. Pipet 0.25 mL of a urine sample into the test tube; allow 5 min for the digestion of the sample at room temperature. Add enough distilled water to bring the final volume to approximately 30 mL; the final volume is not critical.

Transfer the diluted sample to the reaction vessel. Attach the vessel to the bubbler. Inject 0.5 mL of 10% stannous chloride solution into the reaction vessel. This closed system eliminates the possibility of mercury loss from the sample to the atmosphere.

Immediately press SAMPLE START—the system automatically rezeroes and aeration commences. The 60-sec cycle will automatically go to completion, and the mercury value will be displayed in nanograms with the reading held until the next sample cycle. Data can also be displayed on a chart recorder or entered into a computer.

Forty urine specimens with an average mercury concentration of 50 μg/L can be analyzed before film saturation occurs.

Summary

The incorporation of thin gf sensors into an analytical system designed for the determination of total mercury in an aqueous matrix represents a distinct improvement over the AA method. The integrating characteristics and the selectivity of the gf sensor to a mercury signal are the major reasons for this improvement.

Determination of Nanogram Quantities of Mercury in Liquid Matrices by a Gold Film Mercury Detector

P. J. Murphy

Industrial Laboratory, Kodak Park Division, Eastman Kodak Company, Rochester, New York 14650

Many papers have been published in recent years dealing with mercury analysis. One of the most significant mercury methods was developed by Hatch and Ott (*1*), who reported that mercury could be directly reduced to the elemental state in an aqueous medium and the mercury vapor measured by atomic absorption spectrometry. Another important technique was developed by Anderson (*2*), who demonstrated that mercury could be collected on gold for subsequent determination by atomic absorption. McNerney (*3*) and Ohkawa (*4*) have taken advantage of the amalgamation properties of mercury and gold and utilized a sophisticated instrument based on a change in the resistivity of a gold film detector. However, while this instrument has improved sensitivity (*4*) and analytical versatility, the technology developed using this important nonatomic absorption technique was limited to air samples or those samples decomposed by combustion.

It is the purpose of this paper to describe the use of a gold-film mercury detector coupled with a direct reduction technique to determine mercury in aqueous media. The system allows analysis of a wide variety of samples while eliminating most of the interferences usually associated with cold vapor atomic absorption techniques.

EXPERIMENTAL

The instruments used in this study were a Gold Film Mercury Detector, Jerome Instrument Corporation, and a Coleman MAS-50, Coleman Instruments. Additional equipment included Coleman MAS-50 aerators and Standard 500-mL BOD bottles.

Two reducing agents were employed: tin(II) chloride solution (10% in 10% HCl) and sodium borohydride solution (0.2% in 40% NaOH). The standard solution used was prepared using reagent-grade mercury sulfate.

All other chemicals used were reagent-grade and "mercury-free" and included acetone, sodium sulfite, sodium thiosulfate, pyridine, ammonium hydroxide, hydrochloric, nitric, and sulfuric acids.

RESULTS AND DISCUSSION

Figure 1 shows the adaptation of a gold film mercury detector set up to monitor mercury in aqueous solutions. In this system, mercury vapor is volatilized from solution onto the gold collector coil by means of a suitable reducing agent. The collected mercury is then thermally volatilized and collected on the gold films located internally in the instrument. Mercury adsorption onto these films causes an increase in resistance (displayed on the digital galvanometer) and that increase is proportional to mercury content. The instrument is calibrated after each determination using standard addition techniques.

Since the proposed system involves quantitative collection of the volatilized mercury, a time study was needed to determine the optimum collection conditions. Table I shows that 2 min are necessary to complete the collection cycle. The remainder of the data were obtained using the 2-min collection cycle, which begins after introduction of the reducing agent.

Table II shows comparative data of the proposed system and a conventional cold vapor atomic absorption analyzer. The different sample preparations included: Group 1, direct dissolution in water; Group 2, wet digestion with nitric and sulfuric acids; Group 3, direct dissolution in water plus addition of hydroxide (since acidification of sodium thiocyanate with nitric acid is potentially hazardous, hydroxide is added before the addition of the reducing agent. Hydroxide effectively competes with thiocyanate and allows for direct reduction of the mercury); Group 4, use of 0.2% sodium borohydride solution as the reducing agent (mercury forms a strong complex with iodide (HgI_4^{2-}) which keeps the mercury from becoming completely reduced on the acid side with tin(II)

Figure 1. Adaptation of a gold film mercury detector using a direct reduction technique

chloride. Therefore, it is desirable to use a stronger reducing agent such as sodium borohydride in alkaline medium to quantitatively produce atomic mercury. All other data in this paper were obtained utilizing tin(II) chloride as the reducing agent); Group 5, addition of nitric acid followed by boiling (nitric acid addition and boiling allows for degradation of any organic mercury to the ionic state. It also might be noted that the proposed system allows for mercury analysis in water samples at the nanogram per liter level); and Group 6, precipitation of silver with a potassium bromide solution (5). There were no significant differences between the results obtained by the analyzers (correlation coefficient, r_{xy} = 0.9995), except that the gold film system offers lower detection levels (see Groups 1, 3, and 6, Table II).

The chemicals in Table III represent an interference study to show the advantages of the proposed system over cold vapor atomic absorption. Each chemical was dissolved in distilled water and diluted to 100 mL to give the indicated percentage by weight. Mercury and tin(II) chloride were added to the diverse matrices and the element was monitored by both techniques. In each case, erroneously high values were obtained using cold vapor atomic absorption. Gaseous vapors, such as sulfur dioxide and ammonia, which absorb at the 253.7-nm wavelength, showed positive interference. The chemicals listed in Table III are some typical examples of the troublesome types of samples that cause interference in the direct determination of mercury. The attractive feature of the gold film system is that each of these samples can be analyzed directly and accurately without interference from possible gaseous emissions that may be misinterpreted as mercury.

Quantitative Analysis of Mercury Vapor by Gold Film Sensors

by Richard T. McNerney

JEROME INSTRUMENT CORPORATION

PRESENTED AT THE 1983 MEETING OF THE
AMERICAN INDUSTRIAL HYGIENE ASSOCIATION
PHILADELPHIA, PA

The detection of elemental mercury vapor by a thin Gold Film sensor was developed and patented (U.S. Patent #3,714,562) by J. McSherney, founder of the Jerome Instrument Corporation. (Figure 1)

The sensor, produced by high vacuum deposition onto a ceramic substrate, undergoes an increase in electrical resistance proportional to the mass of mercury in a sample. Two films, a reference and a sensor, are placed in opposite arms of a Wheatstone Bridge, a sensitive electrical circuit capable of detecting small changes in resistance. (Figure 2) Since mercury vapor is unique in its ability to alter the resistance of the Gold Films, interferences common to atomic absorption (AA) instruments, i.e. water vapor, SO_2, organic vapors, and particulates, are eliminated.

The Model #411 Gold Film Mercury Vapor Analyzer, designed for the analysis of mercury vapor in the workplace environment, incorporates a pump and digital display with microprocessor control. (Figure 3) Activating either the 10 second sample or 1 second survey mode starts an internal pump which draws a precise volume of air over the Gold Film sensor. The microprocessor computes the concentration of mercury, displaying the results on an LCD meter. This reading remains displayed until the next sample cycle is activated at which point the microprocessor automatically rezeroes the meter.

The microprocessor will ensure a linear response until the Gold Film has absorbed approximately 500 nanograms of mercury. (Figure 4) As mercury accumulates on the sensor, the percentage of saturation is indicated by pressing the Sensor Status button. Approximately forty 10 second or 400 1 second samples can be taken in atmospheres containing 0.1 mg of Hg/m³ (current OSHA TLV) before saturation reaches 100% (500 ng). At that point, a 10 minute film heat cycle is activated to desorb the accumulated mercury from the sensor and return it to its original baseline resistance. (Figure 1)

CALIBRATION

The Gold Film technique determines the mass of mercury per unit volume of sample. Thus calibration of the Model #411 can be performed simply and directly by using the most basic standard possible: the vapor pressure of mercury.

A small drop of liquid mercury in a closed container, e.g. a 300 ml polyethylene or thermos bottle, will saturate the enclosed air at a value which depends only on temperature. (Figure 5)

The concentration of mercury is calculated by utilizing relationships of pressure, temperature, and volume as expressed in the Ideal Gas Law. It should be noted that the concentration is not dependent on atmospheric pressure (P_a), but the vapor pressure of mercury (P_{Hg}) and the measured temperature of air saturated with mercury (T_m). (Figures 6 & 7)

Figure 1

Figure 2

Figure 6

Figure 7

Figure 3

Figure 4

With the calibration vessel maintained at a constant temperature, a known mass of mercury saturated vapor is injected directly into the flow path of the Gold Film sensor of the Model #411 using a gas tight syringe.

Referring to Figure 8, 13.2 ng of mercury is introduced into the Model #411 using this procedure and activating the 10 second sample cycle. With the pump rate set at 0.75 l/min (12.5 cc/sec), the 13.2 ng of injected mercury will be diluted with 125 cc (12.5 cc/sec X 10 sec) of "Mercury free" air. This is equivalent to a mercury vapor concentration of 0.106 ng/cc (13.2 ng/125 cc)*. The digital meter response of the Model #411 is adjusted electronically to reflect this concentration. The linear response of the Model #411 (Figure 10) through its full operational range allows a single point calibration.

* 1 ng/cc = 1 mg/m³

Figure 5

Figure 8

PRECISION & LINEARITY OF THE MODEL #411

The integrating characteristics of the Gold Film sensor, together with microprocessor-control, ensure excellent reproducibility and linear response.

Figure 9 represents a series of repetitive 10-second samples taken by the Model #411 in an atmosphere with a mercury concentration of 0.129 mg/m^3. Sampling was initiated with "Mercury-free" Gold Film sensors and concluded when sensor status indicated 60% saturation. The standard deviation and precision for this set of data is 2.44 and 2%, respectively.

Similarly, the Model #411 sampled atmospheres containing mercury concentrations ranging from 0.010 to 0.375 mg/m^3. Sampling was initiated with a "Mercury-free" Gold Film sensor and concluded when the sensor status indicated 30% saturation. The graph in Figure 10 illustrates the direct correlation between the meter response of the #411 and the known mercury concentration.
